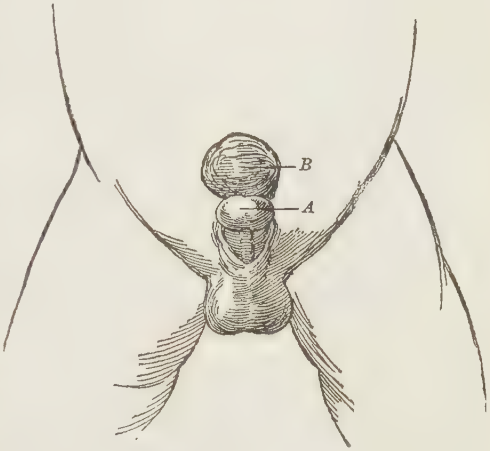
When the deformity is multiple and the scrotum cleft, with a vesical hiatus and a reddened infundibulum, it is not strange that errors are made in the distinguishment of sex.

Sexual desire may be present, but cohabitation is difficult, and I know of no record of fertility in a complete epispadic male.

Diagnosis.—The question of sex may sometimes prove most embarrassing (see Exstrophy, Hermaphrodism, and Hypospadia), but must be determined by a most careful consideration of the predominating external and internal organs which are present.

Prognosis. — Thanks to advances in plastic surgery, not only may cases of uncomplicated epispadias hope to be to a certain extent relieved of their incontinence of urine, but, if a penis of moderate size be present, a channel may be constructed so as possibly to make the man a marriageable being. Even when a sphincter is not secured, the subsequent contraction following an operation and its resultant reflex action on the tube will assist in retaining the urine.

FIG. 25.



EXSTROPHY WITH EPISPADIA.—*A*, malformed penis; *B*, posterior vesical wall.

Treatment.—The treatment should not be delayed after the child reaches the age of four years, for reasons given on p. 633.

Plastic flaps must be secured from the most available site.[1] Nélaton, after the failures of Dieffenbach and Blandin, successfully united the sides of the fissure by freshening the edges of the depression and then reverting across it a long flap with integument inward, which flap was in turn covered by another, taken from the opposite side and placed with its denuded surface against the raw side of the first. When penile tissues are scanty, the scrotum or prepuce may be utilized for flaps, by passing the penis through a slit in the fold.

Thiersch very properly divided the operation into three stages, which division Duplay also adopts.[2]

1. *Straightening the Penis.*—This should be performed early in life, by multiple incision of all restraining bands, in order to facilitate development; but a redundant prepuce should not be sacrificed, as it may be needed for flaps. If a glans penis is present, however, the prepuce should be stripped from it at an early age.

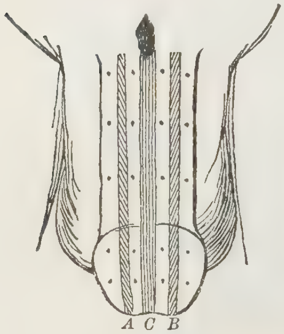
---

[1] Trans. Royal Acad. Med. of Ireland, Dublin, 1888, vi. 306.

[2] Ashhurst's International Encyclopædia of Surgery, 1886, vi. 496.

2. *Formation of New Canal.*—This may be accomplished by Nélaton's plan already mentioned, or by making on each side a wide free denudation of a strip (*A* and *B*) external to the urethral gutter (*C*, Fig. 26), which two raw surfaces are brought together over a catheter, as in hypospadia (Fig. 21), and secured by single shotted wire quilled sutures passing through the tissues, as shown at the black dots (Fig. 26). These sutures should remain *in situ* for five or six days. The new urethra is really formed by approximation of the separated corpora. A catheter inserted through the abnormal opening will assist in keeping the wound clean, but frequent disinfection will be required, as in the operation for hypospadia.

FIG. 26.



3. *Closure of the Orifice.*—This is accomplished several weeks or months later, as described under Hypospadia.

If there is cleft of the pubes or exstrophy, the cure of the two conditions must be simultaneously considered. A number of operations may be necessary before success is attained.

It is well to defer until the end of treatment any purely cosmetic operation looking only to the improvement in form of the penis, as no tissue should be sacrificed until it is positive that it will not be needed for repair.

EXSTROPHY OR EXTROVERSION OF THE BLADDER, ECTOPION VESICÆ, OR HIATUS OF THE ABDOMINAL WALL.

Exstrophy of the bladder (ἐξ, "out," and στροφή, "a turning") is a condition characterized not only by an absence of the anterior wall of the viscus, but also by a deficiency of the abdominal parietes that permits a prolapse of the posterior vesical wall in the form of a reddened mass above the pubes.[1] Non-union of pubic bones, a dwarfed epispadic penis (Fig. 25), cleft scrotum, absence or non-descent of the testes, double inguinal hernia, and various other malformations, usually coexist.

In the female, in whom the deformity is found in the proportion of once in about seven or eight times as compared with the male,[2] a common cloaca may represent bladder, vagina, and rectum.

As uterus and ovaries may be present, however, parturition may take place, as instanced by Huxham and Thiebault.

In another instance the os uteri presented upon the surface beneath the ectopion, and impregnation would have been easy.[3]

When the dwarfed penis is lifted from its bed, the orifices of the ureters can be plainly seen, and in bad epispadic cases the prostatic sinuses, the ejaculatory ducts, and the veru montanum are disclosed.

[1] Journal of Anatomy and Physiology, 1881, xv. 226.

[2] Lancet, 1875, ii. 265.

[3] St. Louis Medical and Surgical Journal, 1879, xxxv. 286.

The opening in the abdominal walls varies from half an inch to several inches in diameter, and the protruding vesical wall (*B*, Fig. 25) always becomes congested from the friction of clothing and apparatus.

The fissure in the pubic bones is sometimes so great that the diminutive penis (*A*) lies almost concealed in the sulcus. The alteration in the anatomy of the parts is well described by Doran.[1]

The lateral portions of the allantois, being diverted from their normal union or arrested in their anterior development, give rise to these strange varieties of malformation, and there is often produced an individual whose sex even is uncertain. As a rule, however, a short search will disclose the presence of distinctive sexual parts, as concealed testicles, spermatic cords, prostate gland, or uterus, etc.

In the male the deformity is usually so great that intromission becomes an impossibility, although sexual desire is often strong.

Practically shut out from respectable society on account of the horrid odor engendered by the decomposing urine that constantly dribbles from the opening, the child becomes morose and morbid, and drifts lower both physically and morally, until by the time that manhood is reached he becomes an object of loathing and disgust to himself and to others, both in his thoughts and in his actions.

Diagnosis.—The diagnosis of the exstrophy is easy, but the determination of the sex may at times be puzzling, except by a careful study of each individual organ present. (See p. 669.)

Prognosis.—A complete cure cannot be expected, but, if a good anterior protection to the bladder is secured, and the urine is directed into a pouch with a small orifice of exit, so that a proper urinal can be adapted, much will be gained both physically and mentally.

When skin-flaps are reverted in childhood, experience has proved that there will be no serious future difficulty from growth of hair within the bladder.

It should be remembered that nearly twenty per cent. of the cases operated upon die from peritonitis, pyæmia, or exhaustion from sloughing of the flaps,[2]—Coulson says twelve per cent.,[3]—but the benefits to be gained from a successful operation are sufficient to warrant the procedure.

Treatment.—*Mechanical.*—In infancy the softest of napkins should be employed, with pads of borated or salicylated cotton or gauze. The greatest care should be exercised to prevent excoriation, by the use of soda or borax water, cosmoline, powders, etc. During the activity of childhood it is almost impossible to apply any urinal with satisfaction, and the simple dressings should be continued until the operation is performed.

[3] Coulson on the Bladder, Wood's Library, 1881.

In older life and subsequently to the operation, some modification of Earle's urinal made of rubber[1] or of metal,[2] so that the cup shall enclose the abnormal opening and conduct the urine into a tube leading to a receptacle strapped to the thigh, will best answer the purpose of cleanliness. (Figs. 27, 28, 29, 30.)

Fig. 27.

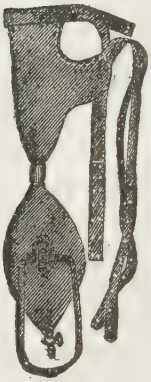

Fig. 28.

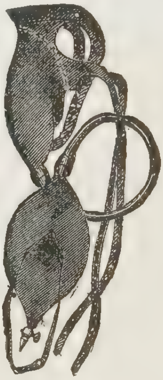

Fig. 29.

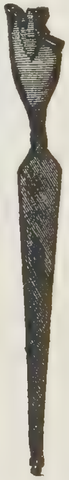

Fig. 30.

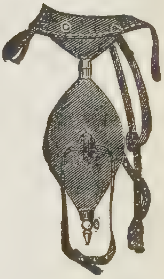

Operation.—Operative procedures[3] should be instituted early, for reasons already given on p. 633.

I. Conversion of the rectum into a urinary receptacle.

II. Plastic closure of the hiatus and collection of the urine at a small outlet.

I. *Diversion of the Urine.*—This plan was attempted by Simon[4] by establishing a communication between the ureters and the rectum by threads. The opening was secured, but the urine still flowed over the pubes, and the patient died in a year from kidney-disease.

Smith[5] turned one ureter into the colon and fourteen months later secured the other in the same position, but the child died on the third day after the second operation, from suppression of urine. The first kidney was entirely destroyed, and its ureteral opening into the colon was impervious.

Lloyd[6] and Johnston[7] both lost their patients by injury of the recto-vesical fold of peritoneum while passing the seton.

Holmes failed to maintain the opening which he had secured by clamp forceps through the vesical triangle. Sonnenberg[1] diverted the urine into the urethral groove upon the dorsum of the penis, and then extirpated the bladder; and Levis[2] established a perineal fistule while he closed the anterior abdominal fissure. His patient died on the twelfth day.

[4] Lancet, 1852, ii.; Holmes, Surgical Diseases of Children, p. 147.

[5] St. Barth. Hosp. Rep., 1879, xv. 29.

[6] Surgical Treatment of Children's Diseases, p. 148.

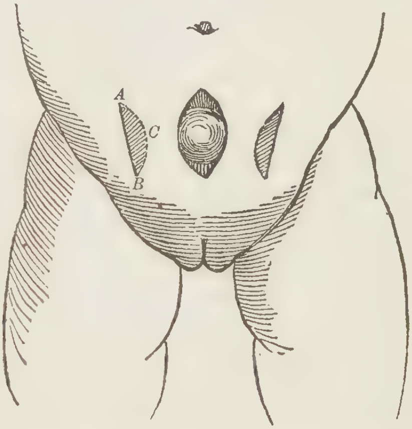
[7] St. Barth. Hosp. Rep., 1879, xv. 29.

As all attempts to divert the course of the ureters or to introduce tubes into their calibres are not only attended with risk but are also followed by kidney-disease, and as the rectum, even in congenital opening of the ureters into it,[3] or in fistule, resents the presence of urine, the use of the bowel as a urinary receptacle seems to be decidedly contra-indicated.

Should the experiments of Fizzoni and Poggi, as practised upon dogs, for the *construction of a bladder* after removal of the viscus, prove sufficiently encouraging to permit its trial upon men, another chance of relief will be offered.[4]

II. *Plastic Closure of the Abdominal Opening.*—If the deficiency is small and the skin movable, as in young children, the edges may be freshened and covered with the raw face of flaps dissected back and drawn directly in from the lateral regions adjoining the opening. Longitudinal incisions made an inch externally, *A B*, will relieve the tension and facilitate union. The gaping cuts, *C*, will heal by granulation. (Fig. 31.)

FIG. 31.



Closure of the hiatus has been successfully done on the third day of life; but infants so young as this bear the loss of blood badly.

Read[5] operated at six weeks on a female child in whom the protrusion of the bladder was through the umbilicus. He reduced the tumor through the hardened encircling ring, dissected up the skin about the opening, as I have myself done in patent urachus, and closed with fine horse-hair sutures, which were removed on the fourth day. Good union was secured, save at one point, where a drop of urine occasionally escaped.

Pancoast's operation, devised in 1858, secures flaps from the inguinal region, which are united in the median line with their epithelial faces inward, the raw surface being left to cicatrize. In Ayres's operation the exposed surface is covered with additional flaps.

Wood's reverting flap, *F*, is in the shape of an inverted U (see Fig. 32), and is taken from the umbilical region above the opening. When turned down and folded upon itself at the line *A B* and sutured at the line *C D*, its raw surface is covered by two lateral flaps. This operation combines the advantages of Pancoast's and Ayres's. When possible, it is better to have the side-flaps large enough to cover in the raw surface and to enclose the base and dorsum of the penis, and also to construct a urethra, if possible, along the dorsum of the penis, as in epispadia. Sometimes the rudimentary penis can have a flap secured for it by thrusting it through an opening made in the scrotal integument.

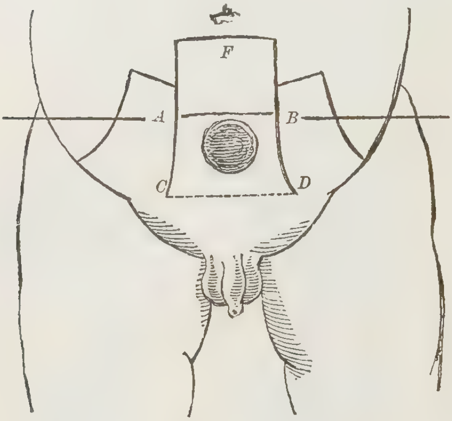
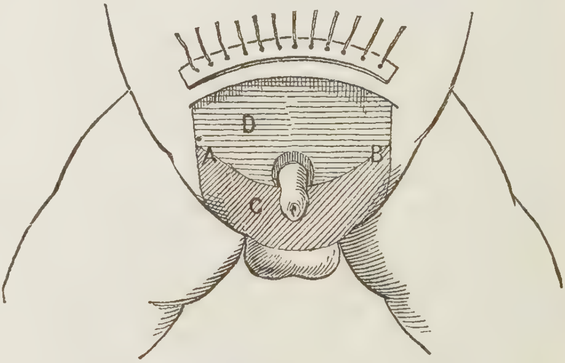
FIG. 32.



Roux and Maury secured a large convex flap of integument from the groin, perineum, and scrotum (Fig. 33, *D*), which, when turned up upon itself and folded at the line *A B*, was secured by tongue-and-groove sutures, after vivification of its cutaneous border, in a groove cut in the abdominal integument above and around the hiatus. The penis was extended through a small slit cut in the flap. This leaves a large raw surface, *C*, but in its cicatrization the orifice of escape is narrowed, and the herniæ are sometimes benefited. The herniæ, however, can be more surely cured by returning them to the abdominal cavity and suturing the rings, as in Macewen's or McBurney's operation.

FIG. 33.



Bigelow denudes the posterior wall of the bladder as low as the ureters, in order to reduce the amount of mucous surface, which he accomplishes by applying upon this raw surface two inguinal flaps with raw tissue inward.

Hare-lip pins, twisted, tongue-and-groove, relaxation,[1] and interrupted-edge sutures[2] are the forms usually employed. Either catgut, silk, wire, or horse-hair may be employed. Perineal cystotomy assists in securing union.

[1] Lancet, 1869, i. 255, and 1874, i. 198; Med.-Chir. Trans., lii. 85, and liii. 187.

[2] Liverpool Med.-Chir. Jour., January, 1882, and Brit. Med. Jour., February 7 and 28, 1880; Gaz. de Sanidad Méd., Madrid, 1879, 365.

Only when it is impossible to obtains flaps from any neighboring region is it justifiable to perform the Trendelenberg operation of dividing the sacro-iliac synchondrosis[1] and approximating the anterior superior iliac spines in order to relieve tension and give a larger mucous lining to the new bladder. When pubic fissure is present, it would be wiser to freshen the bones, forcibly bring them in apposition, and retain them by wiring.

The selection of tissue for the flap will depend upon the mobility of the surrounding skin.[2] In the female, as a rule, the abdominal integument will offer the best district, while in the male the redundant scrotal tissue may be utilized.

The epispadia can be still further closed by a later operation, and a more perfect valve be obtained for retention of the urine, even though the securing of a sphincter is impossible.

It is not to be expected that a cure will be effected without several attempts, and much care and patience will be necessary.

If the operation is performed with thorough antisepsis and weak sublimate dressings are applied, primary union will be best secured. A secondary removable dressing should be applied below, separated from the upper portion by sheet rubber. This can be renewed every few hours and the parts thoroughly cleansed after each urination by a sublimate solution, one to ten thousand. Rushton Parker kept the hips of his patient immersed in a warm boracic-acid bath during the process of healing.[3]

HERMAPHRODISM.

An hermaphrodite (*‘Ερμῆς*, "Mercury," and *’Αφροδίτη*, "Venus") is an individual the deformation of whose genital organs either occasions an uncertainty in regard to sex, or gives the impression that certain of the organs of both sexes are present.

True hermaphrodism—*vera lateralis*—with one half possessing the male germinal gland, or testicle, and the other half possessing the female ovary, is a condition which is rarely if ever present, and its existence must still be regarded as doubtful, in spite of the many apparent cases that have been reported.

Spurious hermaphrodism in its various forms is not uncommon, and the general sexual conformation may be very puzzling at birth, when the presence of certain organs apparently belonging to opposite sexes is observed.

A male with cleft scrotum, undescended testicles, and a diminutive penis certainly bears a closer resemblance to a female than does a case of atresia vaginæ with elongated clitoris, especially if the male penis is hypospadic, with the urethral orifice opening in the perineum.

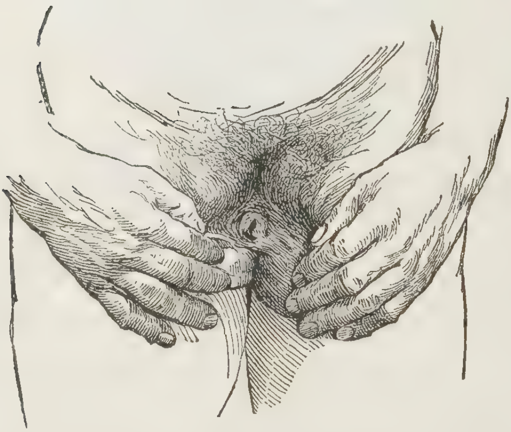
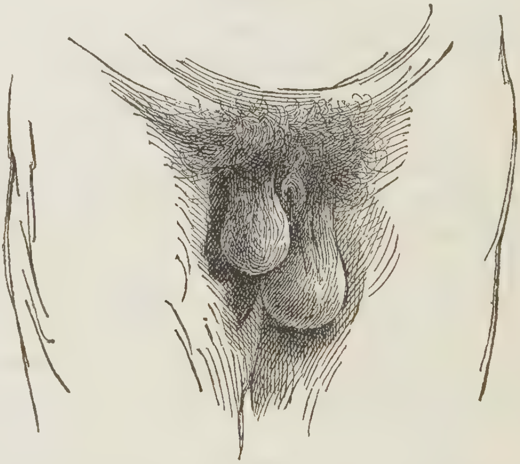
[3] Liverpool Med.-Chir. Jour., January, 1882; St. Louis Med. and Surg. Jour., January, 1881; Ashhurst, International Encyclopædia of Surgery, 1st ed., vi. 338.

Fig. 34.



While the majority of so-called hermaphrodites undoubtedly are hypospadic males, yet the absence of a visible penis is usually sufficient with the laity to cause the baptism of the infant as a female, and the true sex remains undiscovered until adult life is reached, when the descent of the testicles and the development of more masculine tendencies disclose the real character of the person.

Fig. 35.



Such was the case with the individual depicted in Figs. 34 and 35, who for twenty-five years lived as a female in the capacities of domestic, lady's waiting-maid, etc. During childhood the two folds of the entirely divided, non-testes-bearing scrotum doubtless bore close resemblance to the female labia, although now, at fifty-five, the weight of the late-descended testicles and the dragging upon these folds during micturition has made them quite pendulous. When I first saw him, fifteen years ago, no penis was discoverable at first sight, but upon separating the folds a small organ was found concealed at the usual position of the clitoris. This penis was grooved upon the under surface of the glans and gave evidence of the existence of corpora cavernosa, but the spongiosum was absent and the urethral opening was beneath the arch of the pubes. This red-lined infundibulum would admit the little finger, and could easily have been dilated by continued copulation into a moderate-sized receptacle. His sexual desires were always, however, towards females, and, as the penis during erection became nearly an inch in length, he was not only able to procure an emission, but could also render a certain amount of pleasure to the woman, so that after donning male attire he married. His beard appeared at forty, and at present writing, though insane, his figure and all his attributes are decidedly masculine.[1]

Pathogenesis and Etiology.—The study of the embryology of the two sexes shows the great similarity of the component parts and the ease with which errors of deformation may occur during the first two months of intra-uterine existence. Median union of the halves of the uro-genital sinus may be more or less interfered with, or the tubular prolongation anteriorly may be arrested by an altered condition of the external organs themselves, or, again, the primary female perineal fissure may unite and the clitoris undergo abnormal enlargement. (See Hypospadia and Epispadia.)

Heredity is a not infrequent cause.[2] Emmet[3] reports a brother and sister thus deformed. Phillips[4] and Pozze[5] record as high as four cases of spurious hermaphrodism in one family.

In the Museum of the Royal College of Surgery are specimens showing infant twins, each of whom possessed an exceedingly small canal leading up to a uterus and ovaries.[6] A sister was similarly deformed.

Peculiarities of Formation.—Tulpius,[7] De Graaf,[8] Paré,[9] and many other of the older writers describe cases reported to possess the two sets of organs, but they may easily have been deceived, as many of these individuals become for pecuniary reasons very adept in misrepresentation.

Errors in diagnosis are common even in this day, and the most astute diagnosticians have been arrayed upon opposite sides.[10]

The well-known case of Catharine or Carl Hohmann was examined by such able men as Recklinghausen, Friedreich, Virchow, Schultze, Mundé, and Rokitansky, and is probably as nearly a case of true lateral hermaphrodism as any on record.[11] As a child she passed as an undoubted female. Developing at twelve years of age, at seventeen she showed strong sexual affinities for males, which she gratified for twenty years in a cleft, although she possessed no vagina. All her characteristics were feminine, and several physicians report that they actually saw menstrual blood exuding from the urethra. Menstruation is said to have occurred regularly for twenty years. Upon the right side was a well-formed testicle in a scrotum; in the left inguinal region was a body, and to the left of and behind the small penis was another mass, which two bodies were inferred by some physicians to be ovaries, but the question cannot be determined except by post-mortem in the future. In his female capacity the sexual orgasm gave a thrill upon the left side, according to *his* statement, which must be taken with "many *large* grains of salt." At forty, male characteristics appeared, and he subsequently married a woman, with whom, as his penis developed, he was able to produce the emission of a fluid containing spermatozoids.

Parsons[1] describes an individual with a prolapsed ovary in the right labium and a similar undescended organ in the left groin; yet these were more probably testicles, or they may have been similar to the masses found post mortem by O'Neill[2] to be a hardened congenital omental hernia on one side and a mass without glandular structure on the other.

Palmer[3] alludes to an autopsy by Meyers, where a withered testicle existed on the right side with penis and prostate gland, while on the left side was an ovary with Fallopian tube and uterus.

Even post-mortem examinations, when analyzed, are not as convincing of the dual nature as would seem from first glance. Stoneham,[4] for instance, reports the examination of a child who died from strangulated hernia. The external organs are said to have been of the male type, but, as there were no testicles, the supposed penis may have been simply a clitoris. A prostate gland enclosed the neck of the bladder, and behind this were a vagina and a uterus with cervix but without external os. On either side of the uterus lay organs that are denominated testes, but, as the physician fails to account for any ovaries, it seems much more probable that they were malplaced ovaries, especially as the Fallopian tubes were present. An epididymis is said to have existed.

The case certainly does not prove the existence of the two essential organs, testes and ovaries, and I have discovered no instance on record where dual procreative power has existed.

Heredity is well instanced in the facts that two brothers of this case had penis and scrotum without testes, and that a sister possessed bifid nipples.

Burnet[5] also reports a post-mortem in which testicle, ovary, prostate gland, and uterus were present; but Woodward thinks that the ovary was only a mass of adipose tissue, and that the so-called uterus and vagina represented the united vesiculæ seminales, the conformation of which was irregular in consequence of the arrest of development due to non-descent of the testes. Huffner[6] also reports a child dying at ten months in whom both testicles and ovaries were present.

[6] Centralbl. f. d. Med. Wissensch., January 3, 1871.

Willcocks[1] gives the results of a post-mortem upon a *supposed* female child, in whom testicles and vas deferens were present but no female organs existed.

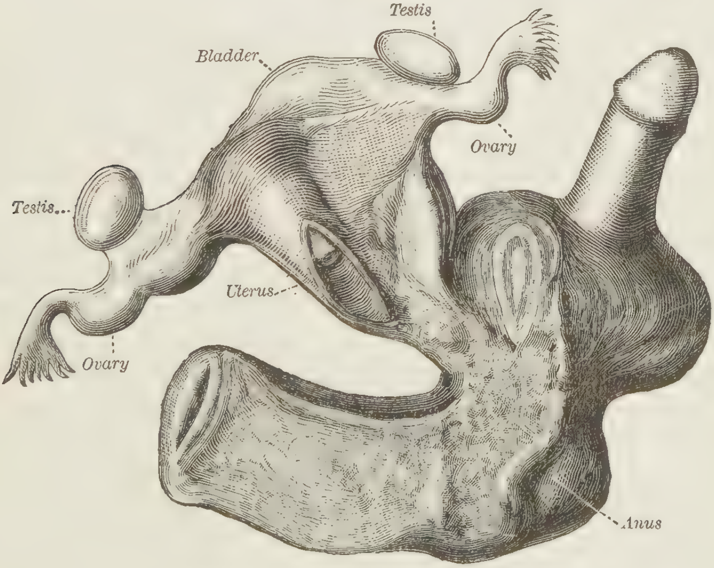
The constantly-found condition of a prostate gland in males is not a positive diagnostic sign, since, in a case where a mass of dense fibrous tissue existed at the neck of the bladder, a committee of the Pathological Society of London decided that it was not a prostate, since neither sinus pocularis nor veru montanum nor ducts were present.

Barnes records a post-mortem upon the body of a child who died at three weeks, in whom a hypospadic opening had existed at the frænum of what appeared to be a penis but was really a clitoris. There were neither uterus nor ovaries present.

In Tidy's "Legal Medicine," Mann's "American System of Gynæcology," the *New England Medical Monthly*, 1883–84, p. 342, and 1884–85, p. 1, Simpson's "Anæsthesia, Hermaphrodism," etc., 1871, Edinburgh, and the "Dictionnaire des Sciences Médicales" (article Hermaphrodism), will be found the records of cases that have puzzled the most astute anatomists.

Fowler[2] exhibited to the New York Obstetrical Society, for Drs. Avery and Sayre, the cast of the pelvic organs of a supposed male who was reported to have menstruated through his penis. Fig. 36 is from this cast, and shows the organs undoubtedly of a female with probably a large clitoris. It is also definitely stated that the person possessed feminine characteristics. Being interested in arriving at the possibility of the exist-

FIG. 36.



---

[1] Trans. Path. Soc. Lond., 1884, xxxvi. 309.

[2] Amer. Jour. Obstet., 1887, 423.

ence of the two masses labelled "testicles" and "ovaries," I wrote to Dr. Fowler to learn whether these had been proved to be such organs.

His reply was as follows:

> I found a wax model of the alleged hermaphroditic organs among some old rubbish, traced the case to Dr. Sayre (to whom it had been sent by Dr. Avery), and learned all that has been stated in the *American Journal of Obstetrics.* Sayre had the model made from the specimen sent him in alcohol, and declared that the organs which I have labelled ovaries and testes are such. Of course I asked whether a microscopic examination was made, and the reply was that it was not, because very few had such an instrument in those remote days. So you see this case, as remarkable as it appears to be, falls in with the rest of its kind. Yet, were you to see the cast, I am sure you would be "almost persuaded."
>
> Very truly yours,
> GEO. B. FOWLER.

There is, therefore, no positive proof that the masses labelled "testes" are other than adventitious ovaries, or simple non-glandular masses, or malformed portions of a Wolffian body. The duality of sex is in this case, as in nearly all others, certainly not proved, and is more apparent than real.

In Taylor's "Medical Jurisprudence" is also quoted a case with testicle, epididymis, and spermatic cord in the left labium, and a supposed ovary, together with rudiments of a uterus, in the right.

Many of the foregoing cases are instances of hermaphrodism by excess of either male or female organs, or are examples of imperfect bisexual organizations. A few are instances of superposed or crossed hermaphrodism. While these hermaphrodites have frequently become mothers or fathers, there is no instance on record where they have occupied both relations,—*i.e.*, father and mother. Should such a result ever be claimed, it would certainly be open to the widest suspicion of exaggeration and fraud, to which so many of these "professionals" are addicted. It would be very easy for a hermaphroditic mother with enlarged clitoris, who had married a woman subsequently to the birth of her own child, to invite outside male assistance in the impregnation of her wife, and then claim that she was a father; or, even if honest, such "assistance" might be rendered without her knowledge.

Simpson[1] reports the case of a pseudo-female who applied for permission to marry a real woman pregnant by him. Although a husband is reported by Bankin to have borne a child,[2] yet she was undoubtedly a female, and acknowledged to having cohabited with a male.

A hypospadic male with a penis an inch in length, but with an infundibulum two inches in depth between the testes-bearing halves of a cleft scrotum, was found in blissful wifely contentment after twenty years of wedded life with a husband.[3]

[2] Lit. de Hermaphrod., cap. 23, 1609.

[3] Canada Lancet, Toronto, 1883–84, xvi. 134.

The Greeks called these unfortunate beings Tribades, and statues representing various forms of hermaphrodites have been unearthed at Pompeii and Herculaneum.[1]

A spurious hermaphrodite is reported who was considered to have had *two bladders*, a penis connecting with one, while the other was reached by a urethra; but one of them may have been only a cul-de-sac.[2]

For further literature upon the subject the reader is referred to Fisher's "Teratology," to the *American Journal of Obstetrics*, xiv. 94, to the *Journal of the American Medical Association*, October 20, 1888, to the *Journal of Anatomy and Physiology*, London, 1883, xvii. 86, etc.

Diagnosis.—The diagnosis of sex in early childhood is important for reasons already expressed. A careful examination should be instituted, and the sex declared in conformity with the preponderance of existing sexual organs. We are now too far advanced in our means of diagnosis to be guided by Aristotle's rule that "it is to be considered in which member it is fittest for the act of copulation;" but both external and internal organs should be most conscientiously investigated.[3]

An enlarged clitoris[4] is not unfrequently present at birth, and should it continue to grow it may reach even to twelve inches in length.

Cases of superposed or semi-lateral or crossed hermaphrodism are often very puzzling, but care will assist in the formation of a correct opinion.

The absent testicles and the diminutive penis certainly tend to mislead, but I have found the majority of these cases to be varieties of males, which experience, however, differs from that of Parmley,[5] who considers the majority to be females with elongated clitoris. In olden times all these latter cases were classed with hermaphrodites, although they were undoubted females. In the same category also have been classed women who simply had prolapsus uteri[6] or vulvar tumors. The perverted sexualism of these females may induce them to become lovers of women, and to practise Sapphism at an early age. By reason of the pain and inconvenience experienced during coition with men, they may also assume the position of a man, and thus receive and give a certain amount of pleasurable feeling with a woman.

Thus it will be seen that even in later life the direction of sexual desire, while it is of assistance in forming a correct diagnosis, yet is not infallible.

Sexual impulse is mainly dependent upon the presence of testicles or ovaries, but the feeling may be entirely absent, and in this neutral state circumstances may alter affinities. Again, it may be abnormally increased, and may develop as early as four years,[1] and at puberty may lead to excessive degradation.

The absence of proper genital functions may alter the voice and form, the growth of hair, and the characteristics of the individual,[2] but, as these conditions are to be taken in connection only with the study of both external and internal genitalia, they will seldom mislead.

The cases of large clitoris associated with absent vagina or absent uterus, or with uterus emptying into the bladder,[3] are, of course, females minus certain organs; yet in early childhood absolute certainty is impossible.

Cameron[4] mentions a supposed girl who menstruated at thirteen and occasionally for several years later. She married at seventeen, but soon developed masculine tendencies and sought for females. She possessed no uterus, the vagina was but a cul-de-sac, and there were two testicles in the supposed labia.

On the other hand, an *apparent* male may possess a uterus.[5]

Menstruation, if regular and unfeigned, is, of course, presumptive evidence of the existence of an ovary; but such flow may be absent even in an undoubted female, or it may escape through the bladder.[6]

Even where both vagina and uterus were absent, the mons has been found covered with hair at four, the mammæ well developed at ten, and at sixteen the features still girlish.[7]

When cryptorchidism[8] is present with cleft scrotum, as is so common at birth, a careful search must be instituted for the missing testicles. Prolapse of ovaries, even into the inguinal canal, is very rare.

The exceedingly diminutive character of the organs in the new-born renders examination difficult, but with probe and sound distinctive portions even of internal organs can usually be discovered.

If ether is used, great care must be exercised, as the delicate tissues of infancy and childhood are but slightly resistant to the efforts of a strong man. This fact cannot be too strongly fixed in the minds of all surgeons, as many accidents have occurred.

The prostate gland is rarely absent in males, but must not be mistaken for a uterus.

When the sex is uncertain, it would be wise to pronounce the infant a probable male and await developments, since less inconvenience would arise from an error in this direction.

Treatment.—Plastic surgery will sometimes be of service by relieving hypospadia or epispadia or exstrophy, or by unloosing a webbed penis or liberating the organ when concealed, or by removing an elongated clitoris. No rules can be laid down, save that every possible attempt should be made in childhood to instruct these individuals as to their proper sex and to restore the parts as nearly as possible to their normal condition, thus saving them great mental distress and degradation.

The proper time for operation will be between three and six years of age, for reasons given in the discussion on p. 633.

Before removal of an apparently enlarged clitoris the diagnosis of sex should be positive, lest the organ be a male penis.

When the absence of essential organs or the malformation is so great as to preclude the possibility of child-bearing, it is good surgery to unsex the patient at an early age, as discussed on p. 634. The effect, both physically and psychically, will be beneficial. Gross[1] removed the testicles from the cleft scrotal pouches in one case. The child is reported to have had girlish proclivities.

DOUBLE OR SUPERNUMERARY BLADDER.

The condition of double bladder is a very rare one, some even of the reported cases bearing evidence that the second canal leading up to a viscus may have been but an opening into a cul-de-sac.[2] Occasionally, however, the urethræ from two separate male organs[3] enter separate compartments, and in one instance lithotrity was successfully performed in one bladder while the other was healthy.

It is not probable that any treatment will be necessary for such a condition. The only formation likely to give trouble would be in a two-cavity bladder, where the septum existed only throughout a portion of the viscus. In such a case supra-pubic incision would permit examination and possibly partial removal.

ABSENCE OF BLADDER.

In rare instances the bladder may be entirely absent, in which case the ureters will be found emptying into the rectum or vagina, into the urethra directly, or at the umbilicus. A certain amount of contractility is usually present at the outlet, and the ureters sometimes become so pouched and dilated that they are capable of retaining nearly an hour's excretion. Usually, however, the dribbling of urine is constant, as in Winter's case,[4] where the ureters had their exit just inside the imperfect labia of a female child. In Oliver's case the patient reached adult life.[1]

Treatment.—As in exstrophy, partial comfort may be secured by the use of a urinal attached to the body. (See Fig. 27.)

Operative measures have thus far failed to give relief, as the rectum has resented all attempts to convert it into a receptacle for urine.

Should, however, the experiments of Fizzoni and Poggi,[2] as now practised upon dogs, result in the possibility of securing in human beings a like construction of a bladder, there may yet be some hope for these unfortunates.

The application of a truss-pad at the orifice, when feasible, might dilate the ureter into a receptacle, but such a course would probably result in kidney-disease.

OPEN OR PATENT URACHUS.

Open urachus is a condition that is rarely present: individually I have observed but two cases.

The explanation of the fistule is easy. The extra-abdominal and intra-abdominal portions of the allantois in early fœtal life communicate through the umbilicus. When the shrinkage and disappearance of the former occur, and the lower portion of the latter resolves itself into the urinary bladder, there still remains the upper portion of the latter, which in the normal progress of development shrinks and becomes converted during the eighth month into the fibrous cord extending from the top of the bladder to the umbilicus. Failure of closure occasionally occurs, and there then results a small canal that will permit a greater or less escape of urine through its outlet at the umbilicus.

In one of the cases alluded to, this had existed for three years from birth, and the surrounding parts had been kept in a moist, irritated, and eczematous condition from the continuous escape of a few drops of urine.

A careful search will usually disclose the fact that there has been some interference with the free escape of urine, thus giving backward pressure upon the urachal canal and tending to keep it patent.

In one of my cases the labia minora were firmly adherent. A tightly-contracted prepuce might produce the same result, as would also an impacted calculus.

Treatment.—In the case upon which I operated, thorough cauterization of the edges of the fistule had been unsuccessfully tried. I pared the edges extensively and brought the deep parts together with catgut sutures. The wound healed promptly under antiseptic dressings, but in a few weeks reopened, though the flow of urine was greatly lessened. Finding a deep pouch inside of the umbilical ring, I scraped it out thoroughly, cauterized its whole surface with chloride of zinc, pared the edges of the ring, and inserted a drainage-tube to the bottom. This was slowly withdrawn as the granulating process went on, and a perfectly solid closure was secured, which has now been tested for two or three years. A probe could not be carried into the bladder from the urachus, but the issuing fluid was distinctly urinous. There was no obstruction to the exit per urethram save the adhesion of labia before mentioned.

---

[2] Lancet, April 27, 1889, p. 854; also Proc. Sixth Italian Surgical Congress.

Should there be any impediment to the free escape of urine, it should of course be removed before attempting to close the fistule. I did not use the catheter in my case, but instructed the child to urinate every hour for the first week, so as to permit no accumulation.

Bramann reports two cases that had gone on to adult life.[1]

Cysts of the urachus are not uncommon. They are most frequently seen by laparotomists.[2]

DISEASES OF THE BLADDER.

By A. VANDER VEER, M.D.

RETENTION OF URINE.

Retention of urine in children is by no means a common affection. Obviously the chief causes, obstructive lesions, are rarely incident to childhood.

Causes.—Retention of urine can hardly be dignified by the term disease, but is rather a symptom arising from a great variety of causes, among which the chief are nervous, traumatic, congenital, obstructive.

The nervous causes, which cover the greater portion of cases, are either reflex or cerebro-spinal. The cause is reflex in fissure of the anus, rectal polypus, ascarides, hemorrhoids (rarely), phimosis, the action of cantharides, turpentine, and similar remedies, and the free use of anodynes. It is cerebro-spinal in meningitis, hysteria, cerebral tumor, dentition, and Friedreich's ataxia.

Traumatic causes usually arise from blows to the perineum or hypogastrium, fracture of the pelvis, or concussion of the spine.

Congenital defects, such as phimosis, stricture, agglutination of the labia minora, membranous occlusion of the urethra, have been reported in isolated cases as causes.

Obstructive causes are due to stone or tumor acting mechanically.

Pathology.—The pathological conditions lying back of retention from nervous causes are most interesting. In consequence of the intimate connection between the nervous mechanism of the rectum and the bladder, irritation of the sensory nerve-ending of the rectum gives rise through the automatic centre of the cord to irritable bladder or retention of urine. The peripheral irritation from phimosis acts similarly. The administration of cantharides, turpentine, and similar remedies, by an irritation of the sensory nerves reflexly, keeps the sphincter vesicæ tetanically contracted. In certain diseases irritation of the inhibitory conducting paths or of the cortical centres is capable of producing at one time irritability and at another time retention. Such, doubtless, is the case in hysteria, meningitis, and rarely in Friedreich's ataxia.

Symptoms.—The history of the case, the presence of a globular tumor above the symphysis pubis, and the increased tension of the recti muscles, together with dulness upon percussion and possible fluctuation, all go to make a clinical picture not likely to be mistaken.

Diagnosis.—It is barely possible to mistake suppression for retention of urine; the absence of the globular tumor, of the increased tension, dulness, and fluctuation, together with the fever and dry skin, will usually dispel any doubt. However, catheterization makes the diagnosis absolute.

Prognosis.—The prognosis of retention of urine in children is good. Most neurotic affections are but temporary. In organic nervous diseases the prognosis will depend upon the cause. Congenital defects will call for the intervention of surgery. Traumatism is seldom permanent.

Treatment.—A careful study of the case should be made to determine the cause, which in some cases will call for all our diagnostic resources. Treatment is immediate and curative. The first indication is to evacuate the bladder. It is not always wise to resort to the catheter at once. It is difficult to secure the necessary co-operation of children in the use of instruments. Catheterization is not unattended with danger. Rupture of the bladder has occurred from the struggling of the patient, and cystitis may be lighted up even by the most careful. Again, the operation is not regarded as particularly humane by the fond mothers. However, catheterization should be resorted to before damage may be done,—chloroform being administered when necessary.

In purely reflex cases a hot bath followed by full doses of bromide of potash or moderate doses of Dover's powder will usually be effective. In hysteria catheterization should be avoided as long as possible. Faradization of the bladder or the introduction into the rectum of nicely-moulded suppositories of ice every two hours will rarely fail.

Curative treatment will demand the treatment of rectal disorders, the removal of redundant and adherent prepuces, the separation of adherent labia, the division of occluding urethral membranes, and the relief of stricture.

Rupture of the urethra followed by retention and extravasation from perineal injuries should be treated by an immediate external urethrotomy.

Systemic diseases will always call for treatment proper for each disease. Stone and tumors always call for operation.

IRRITABILITY OF THE BLADDER.

Causes.—Irritability of the bladder may be dependent upon—1, diseases of the genito-urinary system; 2, diseases of neighboring organs; 3, disorders of the general system.

Many of the genito-urinary diseases, such as vesical tumor, stone, cystitis, renal calculus, neuralgia, and hyperæsthesia of the neck, are invariably accompanied by vesical irritability. Disorders of the urinary excretion—that is, very acid or very alkaline urine—are causes in rare cases.

Diseases of the rectum and anus, fissure of the anus, polypus, hemorrhoids, an overloaded rectum, ascarides, are frequently causes in children. Adherent prepuce reflexly is a cause of irritability of the bladder.

Dentition, gastric disorders, diseases of the nervous system, and, above all, the uric-acid diathesis, are causes. Prof. E. L. Keyes has given interesting histories of cases of chorea where the bladder was severely affected.

The pathology in some cases is very similar to that of cases of nervous retention, and in others it will depend upon the cause.

The symptoms are frequent urination, tenesmus, and pain, the pain being referred to the perineum, the hypogastrium, or the glans penis,—one or all of these regions.

Diagnosis.—Irritability of the bladder cannot be mistaken for anything else. The only necessary point is to inquire carefully into the cause. In any case where the symptom persists, the bladder should be carefully examined for stone or tumor, and the rectum explored.

Prognosis.—In most cases the prognosis is good, the causes being very amenable to treatment. Cases of neuralgia often run a protracted course. The irritable bladder of Friedreich's ataxia, a rare disease in children, is not greatly benefited by treatment. In hysteria the condition may be refractory, yet it seldom persists.

Treatment.—All treatment should be directed to the cause. Stone, tumor, and phimosis require surgical interference. Cystitis calls for appropriate treatment. Neuralgia will require the use of tonics, electricity, and anodynes, although treatment is likely to be tedious. Hyperæsthesia of the neck will be best treated by counter-irritation by small blisters to the perineum, making the urine bland by the administration of diluents. A small glass of Vichy night and morning and a bland diet are useful adjuvants. The use of hyoscyamus, or of belladonna or its alkaloid atropia, either by the mouth or by the rectum, is sometimes successful. In obstinate cases the instillation of three to five minims of a solution of nitrate of silver (gr. x to ʒi) into the deep urethra succeeds admirably. It should be repeated every week. Cocaine may be used for local anæsthesia. Disorders of the urinary secretion should be corrected. Alkalinity should be combated with the mineral acids and bitter tonics. Benzoate of sodium is valuable in these cases.

In children who have inherited the uric-acid diathesis there is at times irritability of the bladder from a very acid urine. This condition is best combated by the use of colchicum, either the wine or the acetous extract, by the preparations of lithia, or by the alkaline mineral waters.

CYSTITIS.

None of the coats of the bladder are free from the danger of inflammatory changes. The mucous, muscular, and peritoneal coats may be separately or jointly affected. Vesical catarrh or inflammation of the mucous coat is most common in childhood. The disease may be either acute or chronic.

Causes.—Keyes has made a very useful classification of the causes of cystitis,—viz., 1, traumatism, mechanical or chemical; 2, extension of inflammation; 3, exacerbation of pre-existing inflammation; 4, specific action of drugs; 5, neurosis; to which I add—6, general or systemic infection.

1. Fracture of the pelvis, blows upon the hypogastrium, retention of urine, unskilful use of the catheter, the irritation of stone or tumor, all mechanically cause cystitis. An altered urine, very acid and scanty, or decomposing from bacterial infection, may cause cystitis. The use of irritant injections may be a cause.

2. At autopsies on children Henoch has found stone impacted in the pelvis of the kidney, attended with considerable pyelitis. By extension of the inflammatory process the bladder may become affected.

3. In connection with stone, tumor, and abnormal urinary excretion, there is very frequently a variable amount of chronic cystitis. Exposure to cold or errors of diet may in such cases give rise to an active inflammation.

4. The free use of cantharides, of terebinthines, of cubeb, or of the balsams is capable of producing cystitis by direct irritation.

5. Paralysis from spinal curvature, chorea, or reflex irritation from the kidney, rectum, or prepuce may cause cystitis.

6. Cystitis occurs in the course of certain infectious and contagious diseases, typhoid fever, typhus fever, scarlatina, and diphtheria. I feel sure that I have seen it arise from malarial infection.

Pathology.—At the onset of an acute cystitis the mucous membrane of the bladder is hyperæmic, swollen, and secreting a serous fluid. The hyperæmia is likely to be most marked about the neck; ecchymotic spots will be observed, and in the severer cases purplish patches may be found. The mucous glands located in greatest numbers about the trigone are distended with a pearly secretion and surrounded by a dark-red areola. The superficial epithelium exfoliates, leaving erosions. The secretion becomes muco-purulent. The mucous membrane may become gangrenous. Abscess of the muscular coat takes place occasionally in severe cases. There is always more or less ulceration about the neck of the bladder.

There is a class of cases in which the exudation is diphtheritic; coats of the bladder have been expelled by the female. The urine is at first acid, and contains but few pus- or blood-corpuscles, but shows a slight increase of mucus. Later the reaction becomes alkaline, and a greater amount of muco-purulent sediment is found, mixed with blood and epithelial cells.

Symptoms.—The symptoms of acute and those of chronic cystitis differ only in degree. In an acute case the patient's attention is first called to the disease by an uneasy feeling in the pelvis and by frequent micturition. These two symptoms rapidly grow worse: uneasiness gives place to severe pain in the perineum, hypogastrium, back, or thigh: the pain may be located in the glans penis. Micturition becomes more frequent. The presence of urine in the bladder is intolerable, and the secretion is expelled in drops, which may be filled with blood. In children rigors and convulsions are common. From loss of sleep and pain the face has an expression of anxiety; the features are drawn; the depression is very great. If the case does not improve under treatment, rigors recur with greater frequency; the temperature is exacerbated; the skin is covered with clammy perspiration of a uriniferous odor, and jactitations, delirium, and coma supervene, soon to be followed by death.

Happily, few cases are so severe in their symptoms. Cystitis may be of any degree of severity. Chronic cystitis may give very little discomfort; micturition not frequent; pain altogether bearable, except during periods of exacerbations due to cold, excessive exercise, or dietetic indiscretions. Examination of the urine will always give indications of the condition of the bladder.

Diagnosis.—A careful study of the symptoms and an examination of the urine will not allow of a mistake in the diagnosis of acute cystitis. Pyelitis may be mistaken for chronic cystitis, and in many cases the differential diagnosis will be impossible. In pyelitis or pyo-nephrosis the urine is acid and contains pus and epithelium. Especial stress is placed upon the presence of "tailed" epithelium in the urine. Although the bladder may be irritable in pyelitis, the irritability is not likely to be commensurate with the amount of pus in the urine. The pain of pyelitis is likely to be more confined to the lumbar region: there may be localized tenderness and swelling. Bimanual palpation of the bladder will fail to determine undue tenderness. When cystitis is complicated with pyelitis, the diagnosis will be only probable. In childhood chronic cystitis is an indication for exploration of the bladder with a searcher unless another evident cause exists. In this manner diagnosis of stone and often of tumor will be easily made.

Prognosis.—The prognosis in cystitis will be that of the cause. Many of the causes are very amenable to treatment. The greater proportion of cases get well in from ten days to two weeks. In cases where there is a diphtheritic exudation the prognosis is bad. Chronic cystitis arising from spinal caries can be only palliated. The treatment of cases of chronic cystitis is, at the best, tedious, and there is liability to relapse.

Treatment.—The primary indications in the treatment of acute cystitis are rest in bed, relief of pain, and administration of diluents. A hot bath should be given at the onset, and repeated daily if possible. The bowels should be kept open by the administration of mild aperients (avoiding aloes) or warm-water enemas. Careful attention should be paid to the diet, only plain food, preferably fluid, being allowed. Acids, stimulants, and fruits should be prohibited; meats must be given very sparingly; melons may be allowed *ad libitum.* Quinine and iron should be administered in tonic doses. The tincture of chloride of iron in ten-minim doses is the most eligible preparation. Quinine may be given in pill form, two grains every four hours. Hot anodyne poultices should be applied to the hypogastrium. The patient should be kept in bed, with the hips elevated by means of an air cushion or a hard pillow. Opium in combination with belladonna should be given, preferably by suppository, in sufficient quantity to relieve pain and procure sleep. The citrate of potassium should be given dissolved in a glass of Vichy water every four hours. The old prescription of liquor potassæ and hyoscyamus may be substituted. Flaxseed or slippery-elm tea or an infusion of triticum repens may be given for a drink.

In chronic cystitis all the means already recommended will be useful as adjuvants in the treatment. Fluid extract of corn-silk in combination with benzoate of sodium enjoys considerable reputation as a remedy. The fluid extract of pichi in my hands has been worthless. Counter-irritation by means of blisters or by the point of the Paquelin cautery applied to the hypogastrium should not be lost sight of: it often does good.

Finally, the bladder may be washed out with warm borax-water, a solution of benzoate of sodium (ʒi to Oi), or an infusion of golden-seal. In cases where there is a great amount of purulent secretion a solution of acetate of lead or chlorate of potassium may be employed in the irrigation with good results.

TUMORS OF THE BLADDER.

Primary new growth of the bladder is especially rare before puberty. After a somewhat extended examination of the literature of vesical new growths, I have been able to collect the histories of twenty-two cases occurring in childhood.

The etiological factors in tumors of the bladder are not more clearly defined than those of tumors situated in other parts of the body. Cohnheim's hypothesis of embryonic remains is worthy of some credence.

Pathology and Morbid Anatomy.—Tumors of the bladder as they occur in children may be thus classified: 1, villous growths; 2, mucous growths; 3, fibrous growths; 4, malignant growths; 5, mixed growths.

Of the twenty-two cases the histories of which form the basis of this article, eleven were mucous, five were malignant, four were villous, and two were mixed growths.

The mucous growths are similar in every respect to soft nasal polypi, and are especially incident to childhood. Winchel found two in the bladder of a child that died a few hours after birth. They may be single or multiple, and are usually pedunculated.

Sir Henry Thompson once said, "Pure fibrous growth in the bladder is a very rare occurrence, known to me only in museums." There is no case known of pure fibroma in children.

There are on record four cases of villous growths in children, including the case where Mr. Bryant removed a small papilloma by its being caught in the eye of a catheter. They do not differ structurally from papilloma found elsewhere. They are not malignant.

Of the malignant tumors of the bladder the case of medullary cancer occurring in a child four years old, reported by Smythe, stands alone as the only instance of primary malignant growth in childhood confirmed by microscopic examination. Secondary sarcoma from the vagina has been reported three times.

Billroth's justly celebrated case of myxo-sarcoma and carcinoma, and another case of fibro-sarcoma, are the only instances of mixed growth that have been reported.

Symptoms.—The classical symptoms of tumor of the bladder are hæmaturia, irritable bladder, and pain. In ten of the twenty-two cases whose histories I have collected, hæmaturia was a symptom. Aside from villous growths, tumors of the bladder in children are not attended with hemorrhage, as a rule. Hæmaturia, when it occurs, is an important symptom. In villous growths it appears early and varies greatly in amount. It may be but a few drops at the end of the act of urination, or may be sufficient to endanger life. The hemorrhage is not dependent upon the size of the tumor. Exercise does not increase the amount or frequency of the bleeding. Hæmaturia is nearly always a late symptom of malignant tumor if it appears at all after breaking down has commenced.

Irritable bladder is always present. It may vary with the situation and size of the growth, tumors situated at the neck causing much more irritation than those at the fundus. Pain is usually present, and is similar to that arising from stone. Combined with the irritability, it keeps the patient in a most deplorable condition. A mild degree of cystitis occurs from the irritation of a foreign body. Retention of urine may occur from mechanical obstruction. In the female the body of the polypus may be projected from the urethra by some straining. An examination of the urine will often determine detached villi or fragments of the growth.

Diagnosis.—When the tumor is projected from the urethra, or villi are demonstrated in the urine, the diagnosis is easy. Not so with the greater proportion of cases. The symptoms are very often obscure, and are those common to other genito-urinary affections. When the tumor is encrusted with salts the differential diagnosis between it and stone will be impossible. The searcher must be employed with great circumspection. It may provoke in the tumor a very free hemorrhage. On the other hand, it will often clear up an obscure case very readily. A careful and repeated examination of the urine will often be rewarded by the discovery of fragments of the growth. As there is no specific cancer-cell, isolated epithelial cells have no diagnostic value. In Billroth's case the tumor could be easily felt above the symphysis pubis. Where symptoms persist although a positive diagnosis cannot be made, an exploration is desirable.

Prognosis.—At present no data can be found upon which to base a prognosis. Until recently few operations were undertaken for the relief of vesical tumor. Surgeons were content to palliate and temporize. Under the old method of treatment the prognosis was bad. Of the twenty-two cases reported, seventeen died and five recovered. Operations were undertaken in ten cases. Billroth's case, a boy twelve years old, recovered. Two others recovered through the accidental removal of the growth in the eye of a catheter. In the other two cases of recovery, occurring in females, the urethra was dilated and the tumor removed. Cases are likely to be complicated by cystitis, ureteritis, pyelitis, and pyo-nephrosis. In malignant tumor the cachexia develops.

The revival of supra-pubic cystotomy and the growing tendency of surgeons to interfere actively in cases of vesical tumor will improve very greatly the prognosis of this hitherto fatal disease. Aside from malignant growths, the mortality ought not to be above thirty per cent.

Treatment.—Operative treatment in cases of simple tumor of the bladder gives the only hope of cure, and in all cases it affords temporary relief. Sir William MacCormac, in the discussion of the relative merits of supra-pubic and of perineal cystotomy, said, "I believe that in children the greatest future development of supra-pubic operation will occur." In childhood the bladder is nearly an abdominal viscus. From reasoning it would seem that supra-pubic cystotomy is the better operation in children. The use of the colpeurynter raises the bladder well out of the pelvis.

When an operation has been decided upon, the utmost care must be taken to place the patient in the best possible condition. The bowels should be freely opened by laxatives or enemas. Attention should be paid to the state of the urine, and every effort made to render it aseptic and acid. The site of the operation should be shaved and made thoroughly aseptic. The following instruments are necessary: a continuous-flow syringe, a small rectal colpeurynter, a scalpel, half a dozen pressure-forceps, a grooved director, two large full-curved Emmet needles, long polypus-forceps, a wire écraseur, a Volkmann's spoon, curved scissors, a good cautery, a sponge-holder, a retractor, drainage appliances, catgut, chromic acid, solution of subsulphate of iron, etc. A good apparatus for illuminating the bladder will be useful.

The anæsthetic having been given, the colpeurynter is introduced into the rectum and distended with not over five ounces of water. The bladder may be moderately distended with warm boro-salicylate solution. A hard pillow being placed under the pelvis, the abdominal viscera will gravitate away from the bladder. The first incision, from two to three inches long, should clearly divide the skin, fascia, cellular tissue, and linea alba from above downward to the border of the symphysis pubis. The recti muscles should be separated with the handle of the scalpel, when the transversalis fascia may be picked up with a forceps and divided upon a grooved director. The perivesical fat, behind which lies the peritoneum, should now be gently lifted upward with the finger, exposing the bladder. The site of the incision having been selected, two loops of strong silk should be passed through the bladder-walls by means of the Emmet needles, for the support of the bladder. These loops should be intrusted to an assistant. The incision into the bladder large enough to admit freely the index finger should be made with a knife, and quickly followed by the exploring finger, so that a knowledge may be gained of the character of the tumor and its attachments before the fluid escapes. The method of removal—by the forceps, spoon, or écraseur—will depend largely upon the attachments of the tumor. Each case will require more or less operative ingenuity. Hemorrhage may be very embarrassing: a firm sponge-probang dipped in a solution of subsulphate of iron and applied to the base of the tumor for a moment will in most cases control it. When the hemorrhage is controlled, a small electric light can be used with advantage in the exploration of the bladder, especially if the pelvis is raised high. In every case where possible, the base of the tumor should be thoroughly destroyed, for which purpose there is nothing more satisfactory than the galvano-cautery. Chromic acid may be used, but it is difficult to localize its action.

The question of the closure of the wound must be decided for each case separately. Where the mucous membrane of the bladder presents no gross evidence of inflammation and the traumatism is not very great, the bladder should be closed. In the severer cases the method pursued by Prof. Hunter McGuire—namely, the establishment of a urinary fistula above the pubes—seems most feasible. A small male catheter may be left in the fistulous tract for a few hours, until the borders of the wound glaze.

In the after-treatment the patient may be allowed to assume any positions he chooses. The diet should be bland, chiefly milk. Careful attention should be paid to the urine, keeping it acid, if necessary, by the use of acid drinks. Acid urine is aseptic urine. The wound will require frequent changes of dressing to keep it clean.

In the female, small pedunculated polypi situated near the neck may be safely removed by dilatation of the urethra and the use of the forceps or the snare.

DISEASES OF THE UMBILICUS.

BY WILLIAM LEE, M.D.

As upon the proper management and treatment of the umbilical cord largely depends our ability to avoid many accidents which are incident to its separation, no apology is needed for opening this article with a short treatise on the subject. Indeed, it would seem that too much cannot be said in order to induce the careless physician to attend personally to the management and treatment of the cord, and not—as is too often the case—be eager to throw on the monthly nurse the whole responsibility of dressing, etc., of the cord.

In the first place, as a rule, great hurry should not be made to complete the interruption of fœtal circulation; the better practice being to delay a few moments, until the cord collapses and the baby cries.

In applying the ligature, it should be remembered that a thin ligature it liable to cut through the walls of the blood-vessels, and, again, that a thick one will not produce sufficient compression. Not less than three inches should be the distance from the abdominal walls for applying the first ligature, in order to avoid the possible evil effects of the immense muscular power exerted by the umbilical arteries on the inside of the abdominal cavity. The second ligature should be applied one inch from the first, to prevent the oozing of blood on the bedclothes, and the cord cut between them.

According to Dr. A. Jacobi, it is a good rule to apply an additional ligature between the first and the abdominal wall, to avoid hemorrhage, which may take place after the cord has commenced to shrink, from the insufficiently compressed arteries. When tying, avoid pulling on the cord, and keep it as dry as possible.

In cases where the cord is very thick and vascular, my rule is, to sever before the ligature is applied, and, if possible, empty the cord of blood and serum, as by this means the amount to be sloughed off can be decreased. I then tie, and twist it three or four times, for the purpose of so closing the umbilical vessels as to insure against hemorrhage if the ligature should prove insufficient.

When the cord is severed, its abdominal end should be encircled with a soft piece of linen, covered with a pad of disinfected cotton, and secured on the left side of the abdomen by a flannel bandage wide enough to go over the large part of the chest and abdomen, so as to prevent slipping.

In dressing the cord, all oily or greasy substances must be prohibited, and it must not be allowed to remain wet from urine or otherwise, as in either case, instead of desiccation, there will be decomposition of the cord and inflammation may extend to the navel.

The habit which most nurses have of constantly examining the cord after it is dressed must be forbidden, as it is in this way, I am satisfied, that septicæmic troubles often have their origin: it should be examined only in the presence of the attending physician. The usual time at which the cord shrivels is from two to four days, and this, if nothing prevents, is followed by its rapid desiccation, and falling off between the fourth and the eighth day. No infallible rule can, however, be laid down, on account of the nature of the cord and the particular constitution of the children. A soft, large, and fat cord shrivels slowly, even suppurating at its base before separation; while, on the other hand, a thin, small cord will often dry up early and become transparent, show the dried vessels, and separate without suppuration.

Various theories have been advanced in regard to the detachment of the cord: according to Haller and Munro, it is due to a kind of gangrene; Gardin considers it the result of constriction of the epidermis; Chaussier ascribes it to an inflammatory process; and Billard, to traction of the abdominal muscles which separate the navel from the dried portion of the cord.

When final separation of the cord is completed, the child's abdomen presents an infundibuliform depression, with a more or less decided ridge, formed by the skin, which is still a little reddened or inflamed, and there remains a slight oozing which soils the linen: the cicatrix is not perfect and entire until the tenth or the twelfth day. Should the cicatrization be very slow, a small quantity of some stimulating powder can be dusted on the part, as bismuth subnitrate, salicylic acid, iodoform, etc. Carbolic acid, as first stated by Dr. A. Jacobi, must not be used in treating abrasions, etc., of infants, as they are very susceptible to its poisonous properties. Neither should we use perchloride of iron, as the hardened coagulated mass formed by its application favors accumulation of secretions, which becoming absorbed give rise to sepsis.

If no unforeseen accident occurs, the navel, after the twelfth day, becomes more and more formed, and the umbilical vessels contract, drawing the cicatrix inward, so as to depress it, while externally the plumpness of the child causes it to appear still further depressed.

The cicatrix should be bandaged not only upon general principles, but also because in this way umbilical hernia can be obviated by protecting the abdomen and avoiding a strain when the child cries, coughs, or is handled roughly.

THROMBOSIS, PHLEBITIS, SEPTICÆMIA.

After the cord is ligatured, the greater portion of the blood in the umbilical vein flows into the circulation, and that remaining forms into small clots or thrombi, which, upon contracting, harden and remain inert, or soften and dissolve. Should, however, the formation of these clots or thrombi terminate in thrombosis of the umbilical vein, putrefactive changes may take place, and particles of the disintegrated fibrin enter the circulation and produce phlebitis, embolism, or septicæmia in its worst form.

The best exposition of the history of thrombosis and the action of thrombi is that given by Prof. Ernst Ziegler,[1] who writes as follows on the issues of thrombosis.

"The fully-developed thrombus is a somewhat firm and dry mass adhering to the lining membrane of a vessel or of the heart, its color and structure varying as we have described. The comparatively small quantity of liquid it encloses is explained by the fact that the fibrin after its separation always shrinks, and so squeezes out the liquid from its meshes. This shrinking, when it occurs in an obliterating thrombus, may leave the channel of the vessel open once more. In many instances the contraction due to shrinking is very considerable. The fibrin is transformed into a dense mass, which may persist unchanged for a long time and ultimately becomes calcified. It is thus that the chalky concretions called phleboliths are formed in the veins. In the same way thrombi which are seated on roughened surfaces in the aorta or valves of the heart may become calcified, and may become sheltered from secondary deposits by the growth of an endothelial covering over them.

"Contraction with calcification is what we may call a favorable issue of thrombosis. The very common issue of thrombosis in softening is much less favorable. Softening is distinguished as simple or red softening and puriform or yellow softening. In simple or red softening the central parts of the thrombus are first of all changed into a grayish or reddish pulp, consisting of broken-down and shrunken red corpuscles, pigment-granules, and colorless granular detritus. If the softening then extends to the surface-layers, and if the blood-current is still flowing over the thrombus, the products of disintegration may be carried into the general circulation. This occurs both in the case of cardiac polypi and in venous thrombosis, especially when the tip of a thrombus projects from the orifice of a small vein into the channel of a larger, in which the blood is still flowing.

"The most unfavorable issue of all is the puriform or yellow softening of the thrombus. In this case the thrombus is transformed into a dirty- or reddish-yellow, fetid, pus-like cream or pulp. This contains a multitude of pus-corpuscles and a large proportion of a finely-granular matter, which consists in part of fatty and albuminous detritus, and in part of micrococci. The latter frequently form groups or colonies, and are probably to be regarded as the exciting cause of the softening process. Such puriform thrombi act destructively on the surrounding tissues and set up inflammation. The intima of the vessel becomes turbid or opaque, and suppurative inflammation begins in the tunica media and tunica adventitia, extending to the tissue enclosing the vessel. Soon the entire thickness of the vessel-wall is infiltrated and takes on a dirty-yellowish or grayish appearance. Ultimately the tissues undergo putrid disintegration. If the puriform matters are carried by the blood-current to distant spots, they there produce necrotic and putrefactive changes in the tissues and set up suppurative inflammation. The entire process, in which puriform softening of a venous thrombus is associated with suppurative inflammation of the vessel-wall, is described as purulent thrombo-phlebitis. It is due in the first instance to the causes which lead to the thrombosis, and in the second to the access of micrococci to the thrombus. In the other cases the inflammation of the vessel-wall is primary, and the thrombosis a secondary effect. The purulent form is most commonly met with in the neighborhood of septic wounds and ulcers. The most favorable issue of thrombosis is in organization of the thrombus. By this is meant the replacement of the fibrin and corpuscles by vascularized fibrous tissue."

---

[1] Text-Book of Pathological Anatomy and Pathogenesis, Wood's Library, Part II. p. 10.

Phlebitis is usually caused by the entrance of air into the umbilical vein from the umbilical fossa, which, becoming impregnated with germs from the atmosphere, gives rise to the products of inflammation of the vein and of the tunic of which it is composed. Again, direct infection may take place through the vein, in consequence of an ulcerative process commencing about an inch above the navel. At times it is the result of congestion occurring in connection with icterus neonatorum, in which condition we often find the vein filled with pus, giving rise to septicæmia, pyæmia, erysipelas, peritonitis, or cutaneous abscesses. Both phlebitis and septicæmia may arise from soiled fingers, cloths, applications of various kinds, and septic infection from mother or infant, as decomposed lochial discharges, or blennorrhœa oculi neonatorum.

Symptoms.—Besides local inflammation of the vein, the moment the disease is contracted and the infection commences, the child has a chill, high fever, the temperature often running as high as 105° F., loses its appetite, and is constipated. The abdomen becomes hard and painful, particularly in the region of the affected portion of the vein, and, should the inflammation be superficial, a red, livid discoloration is easily seen in the integument over it, and pus is found at the base of the umbilicus. Should the inflammation increase, peritonitis is developed, particularly if it occurs in connection with icterus.

Prognosis.—In cases where the amount of poison absorbed has not been great, and the eliminative process not very seriously interfered with, recovery is possible.

Treatment.—Antiseptic measures must be rigorously enforced from the first, and such special treatment adopted as may be indicated. If pus has formed in the vein, it should be squeezed out and the vessel injected with a mild antiseptic; umbilical wounds should be dressed with disinfecting and stimulating remedies, such as resorcin, bismuth, boracic acid, salicylated cotton, or deodorized iodoform,—resorcin being the best, from the fact that it possesses a special power of preventing putrefaction. I called attention to the antiseptic power of this drug at a meeting of the American Medical Association held at St. Paul in 1883.

Should the mother be suffering from septic poison, the infant must be attended to first, and, if possible, be kept out of the room, at least for two weeks after her confinement. All cloths, sponges, and instruments to be used for the new-born must be carefully disinfected. Internally small doses of calomel are indicated to relieve the constipation, and, that failing, warm-water injections. Generous feeding must be enforced (by a wet-nurse if possible), and alcoholic stimulants insisted upon. (Children take larger proportional doses of stimulants than adults, and with less injurious effects.)

FUNGOUS GROWTHS AND GRANULATIONS OF THE UMBILICUS.

During the first two weeks, and even later, we sometimes find granulating growths cropping out from within the depression of the umbilicus. They appear either as a small polypoid body or as a solid hard tumor, and are usually of the size of a pea.

If not removed promptly, these growths increase in size, and emit a bloody serum, which causes inflammation and makes complete cicatrization of the umbilical stump impossible.

Treatment.—When the growth is pediculated, a small ligature should be carefully passed around its base, and allowed to remain from four to six hours, after which the growth is to be removed in mass with a pair of scissors having blunt points in order to avoid accidents. I use a pair similar to those employed in the operation for tongue-tie.

After removing the growth, touch the stump with a mild styptic and apply over it tightly a pad of disinfected absorbent cotton.

On the other hand, if the tumor is solid and hard, it must be removed by means of cauterization, using for that purpose Paquelin's thermo-cautery or some judiciously selected caustic preparation.

UMBILICAL HEMORRHAGE.

Should the umbilical cord shrink and dry up promptly, we have as a result a cicatrix,—which is the umbilicus. Unfortunately, however, this is not always the case; nature's work is interfered with, and we have, instead, hemorrhage, from either the cord or the navel.

Causes.—These hemorrhages originate from violent traction on the cord in the process of labor, particularly if the cord is short or wrapped around the child's neck. These accidents are comparatively rare, however, hemorrhage occurring, as a rule, either during the last days of the separation of the cord or at a still later period. It may, too, be the result of bad ligaturing, or of disease of the funis, such as an ossified or varicose state of the vessels; again, it may be due to an incomplete closure of the vessels. Malformation or occlusion of the gall-ducts is a fruitful cause of these hemorrhages; so also is the accumulation of bile in the blood, whether from absence of the ducts or from some abnormal condition of the liver which causes suspension of its functions. Associated with bleeding from the navel or cord we may find the hemorrhagic diathesis, as evinced by epistaxis, hæmatemesis, melæna, and purpura hæmorrhagica, the latter being most probably the cause if ecchymoses or petechiæ are found on the lower limbs, the abdomen, and the arms at the time of the umbilical hemorrhage. The following cases will serve to illustrate the manifestation of this hemorrhagic diathesis, also the fatality of umbilical hemorrhages.

Case I.—Mrs. McC. was delivered of her eleventh child—male—January, 1886. The infant was apparently healthy and well nourished, but supposed to have been born three weeks before term. When one week old a hemorrhage from the umbilicus occurred, which proved fatal in about six hours. The blood first came in jets and from the right side of the cord.

Case II.—On May 20, 1888, Mrs. McC. gave birth to her twelfth child—also a male—at full term. The infant was well nourished and healthy. On the morning of the sixteenth day umbilical hemorrhage occurred, the child dying on the second day of the attack, during which time it had four or five hemorrhages. In this case the blood came from all around the navel, was bright in color, and coagulated slowly.

History.—The mother, who had always had natural labors, showed no evidence of tubercular, syphilitic, or other hereditary disease, nor had there, to her knowledge, been any in her family. She, however, complained of being annoyed with frequent attacks of epistaxis, from which, beyond a slight weakness immediately after the bleeding, she suffered no bad effects. The father was healthy, never having been seriously ill. The family were in comfortable circumstances, and out of the twelve children there are seven living, four males and three females. All of the seven are subject to free and frequent epistaxis, the attacks being more frequent with the daughters.

Case III.—In January, 1885, Mrs. S., a chlorotic woman and a victim of uterine disease in its chronic form, was delivered of a quite healthy-looking child. It passed naturally meconium and made water, but shortly after vomited slimy fluid, and was unable to retain food in its stomach long. The infant had from the time of passing the meconium no further action of its bowels, even after injection; its skin gradually assumed a saffron color. The cord came off at the end of the eighth day, and cicatrization of the stump took place without any trouble. On the tenth day the nurse found stains of blood on the right side of the navel, to which I at once applied borate of starch, and no further bleeding took place until the next day, when it became profuse. The umbilical depression was now packed with cotton which had alum previously dusted into it, and the pad secured by a well-arranged bandage, the hemorrhage, however, being controlled but a short time. I next, after gathering up the integument around the umbilicus, transfixed the parts with two needles, and applied strong ligatures, tying them beneath; still the blood oozed, but there was no more decided bleeding. From this time, which was the fourth day, the infant still had spells of vomiting, ejected matter light green in color, became very jaundiced, and died on the fourteenth day.

Autopsy.—Two hours after death the veins and arteries were found to be full of clots. The bladder was very much inflamed. Peritoneum congested, also portion of the small intestines; cæcum packed with fæcal matter, thick, and of dark-green color. Stomach filled with greenish liquid. Gall-bladder distended with bile; biliary duct pervious. Liver very large, particularly the right lobe, and, when cut open, its secretions were very yellow and adhered to the fingers like paste.

Occasionally cases of umbilical hemorrhage are found to be caused by fatty degeneration of the liver, heart, or kidneys, there being a complete breaking down of the blood-vessels. Both jaundice and inherited syphilis are frequent causes of this form of hemorrhage, if not the most frequent cause. Jaundice is a prominent cause, not only because of the impoverished condition of the blood (its globules and fibrin being much below the standard), but possibly also on account of the great accumulation of bile in the system resulting from obstruction of the hepatic or of the common duct. With regard to inherited syphilis, we have, besides the morbid state of the blood acting as a favorable agent to excite umbilical hemorrhage, the various local manifestations of the disease or cachexia from which the new-born suffers.

Sex.—Males are more liable to these hemorrhages than females, the proportion being sixty-six males to thirty-five females.

Age.—In one hundred cases the ages at which hemorrhage occurred were as follows:

First day	4 cases.
Second day	8 "
Third day	7 "
Fourth day	6 "
Fifth to sixth day	28 "
Sixth to twelfth day	20 "
Twelfth to sixteenth day	21 "
Sixteenth to twenty-fourth day	4 "
Twenty-fourth to sixtieth day	2 "
	100 "

Symptoms.—As has been mentioned before, there is more or less oozing of blood during the separation of the cord, according as it is thin or large in size: should, however, the oozing be considerable, we have, as a complication, hemorrhage. Ordinarily the bleeding occurs suddenly without premonition, unless brought about by jaundice, inherited syphilis, or a hemorrhagic tendency.

When hemorrhage ensues, the blood at first flows in an intermittent, dribbling manner, the first evidence being the detection of spots of blood on the child's linen by the mother or nurse, and on further examination a bleeding surface is revealed around the seat of the navel. This bleeding, although appearing superficial, comes from the bottom of the umbilicus, which soon is filled with a putrescent substance mixed with blood. This rapidly increases to hemorrhage pure and simple, and before we are aware the child is exsanguinated despite our best efforts. When umbilical hemorrhage has associated with it jaundice, besides the icteric hue constipation is always present, the stools are white and clay-colored, and the urine is deeply stained with bile. This form of hemorrhage begins at the root of the cord at the time of its separation.

In case of hemorrhage due to malformation of the gall-ducts, the bleeding oftenest occurs first at night, beginning generally from a few hours to a day or two after the navel-string has fallen off. The blood flows with more or less violence, and is most frequently arterial.

Autopsy.—In the details of one hundred post-mortems where death had ensued from umbilical hemorrhage, in twenty-five cases the bile-ducts were absent; in twenty they were open, but there was an abnormal condition of the liver; in thirty the bile-ducts were entirely obliterated and their place was occupied by a small quantity of areolar tissue; in fifteen the bile-ducts were impervious; in ten there was fatty degeneration of heart, liver, and kidney.

Prognosis.—In nearly all instances the prognosis is bad; the exceptions to this rule are those cases in which the family history is good. The cases most apt to be fatal are those in which the hemorrhage proceeds from or is connected with general septicæmia, jaundice, congenital syphilis, or purpura hæmorrhagica. The duration of life in fatal cases ranges from two to six days.

Treatment.—If the bleeding is slight it may easily be arrested, but even then we must not lose sight of the possibility of hemorrhage recurring at any moment. A good rule, and one which I always adopt, is to instruct the nurse how to pinch up the umbilicus between her fingers and by firm pressure control the bleeding until assistance arrives.

Hemorrhage can sometimes be stopped by injecting a mild styptic into the open vessels and applying a suitable compress. In all cases constitutional as well as local measures must be resorted to.

Internally Dr. J. Foster Jenkins recommends small doses of calomel, not only for its laxative effects, but also because the remedy acts as a derivative. When there is a hemorrhagic diathesis, nux vomica often does well; also iron,—preferably the tincture of the chloride, to which may be conjoined either ergot or digitalis. The most useful local remedies are alum, borated cotton, styptic cotton, cold or hot applications, nitrate of silver, plaster-of-Paris cuirass, and lint soaked with the perchloride of iron.

Failing to suppress the hemorrhage by ordinary measures, we finally resort to the more effectual,—namely, that of transfixing the integument at the base of the cord, so as to include the umbilical vessels. This is done by passing through the parts, at right angles, two well-carbolized hare-lip pins or needles, and securing them tightly beneath with strong ligatures wound in the figure-of-eight form.

At the end of five or six days remove the needles and apply oxide of zinc or some simple ointment.

DISEASES OF THE TESTES AND PENIS:

HYDROCELE; RETAINED TESTIS; TUMORS OF THE TESTICLE; BALANITIS; URETHRITIS; MASTURBATION.

By F. R. STURGIS, M.D.

HYDROCELE.

THE testis is covered by two tunics, which are known respectively as the tunica vaginalis and the tunica albuginea. The tunica vaginalis is a closed serous sac which is derived from the processus vaginalis peritonei, and is divided into two layers,—the visceral and the parietal. The first of these lines the scrotum, and the second envelops the testis and is in close relation to the tunica albuginea. At the birth of the child the connection with the peritoneal cavity which formerly existed is usually closed, but sometimes this is not the case. This portion of the tunica vaginalis envelops the head and body of the epididymis, and in the normal condition contains a few drops of serum between the two layers.

HYDROCELE OF THE TESTIS.—Hydrocele is defined as an effusion of serum between the two layers of the tunica vaginalis, and in infants and children may be divided into the congenital and acquired varieties. Congenital hydrocele is due to a more or less incomplete closure of the processus vaginalis peritonei, which allows serous fluid from the peritoneal cavity to settle in the vaginal sac. The acquired variety is due to the accumulation of serum from inflammatory or other causes between the parietal and the visceral layer of the sac.

CONGENITAL HYDROCELE is due, as stated above, to non-closure of the canal leading from the abdominal cavity into the scrotum. This canal is sometimes wide and at other times narrow, and admits of fluid being passed from the scrotum into the abdominal cavity, and *vice versa*. It may be mistaken occasionally for hernia, but the only point of resemblance is the fact of its reducibility, and it is easily distinguished by its translucence, the feeling of tension and elasticity, and the absence of the gurgling which is nearly always present if intestine has passed into the scrotal cavity; it is furthermore to be distinguished from an omental hernia by the difference in the feeling of the two, by the absence of the firmness and hardness which characterize an omental hernia, and by its capacity for transmitting light. Sometimes the testicle bulges out the posterior portion of the scrotum, from pressure of the hydrocele above, and sometimes the testicle is retained in the belly or the inguinal canal, from the pressure of the enclosed fluid in the serous sac beneath.

ACQUIRED HYDROCELE.—In acquired hydrocele the accumulation of serum between the layers is due sometimes to injury or inflammation and sometimes to closure of the communicating canal between the tunica vaginalis and the abdominal cavity, thus converting the congenital into the acquired form.

This variety may be either acute or chronic, the latter being usually the sequence of the former. During the acute stage there is comparatively little change in the condition of the sac, and the fluid is clear and serous. But when it becomes chronic the walls of the sac are thickened and lined with false membrane, and the fluid becomes turbid and albuminous. If during the chronic stage acute inflammation supervenes, cure may result from the absorption of the fluid and cohesion of the walls of the sac; but in some instances this cohesion is only partial, and the hydrocele then becomes what is known as the sacculated variety. Sometimes blood is effused into the cavity of the sac from an injury, such as a blow or fall, and then there is produced what is known as hæmatocele.

HYDROCELE OF THE CORD is caused by a collection of fluid in the middle portion of the processus vaginalis. If the processus vaginalis is closed above and below, the hydrocele is of the encysted variety; but if the opening with the abdominal cavity still exists, it is called a communicating hydrocele. An encysted hydrocele of the cord may reach from the internal ring into the scrotum, and is then known as a complete encysted hydrocele; but if the hydrocele is only partial, it is intra- or extra-inguinal, according as it is within or without the inguinal canal. This kind of hydrocele assumes various forms, being oblong, spindle-shaped, or round.

Hydrocele herniosa is simply a hydrocele of the cord which is complicated with an inguinal hernia.

Causes.—The congenital variety of hydrocele is common during the first year of extra-uterine life, and forms a large proportion of the hydroceles seen in young children. It is probably due to intra-uterine changes which are not as yet completely understood. The acquired form is rarer in children than the congenital, and is due to pressure or injury or is a sequence of some disease of the testicle. Hydrocele of the cord is caused by a patent condition of the processus vaginalis peritonei, and is sometimes the result of perispermatitis, of local injury to the cord, or of retained testis. It is present in ten per cent. of all cases of hydrocele, and is found usually in the first year of extra-uterine life, sometimes in the second, and very rarely later on.

Symptoms.—The principal symptom of hydrocele is the presence of a swelling in the scrotum which is elastic and transparent if the contents of the sac be serous, and gives a decided sense of fluctuation. If the hydrocele is congenital, the fluid can be compressed into the abdominal cavity and the scrotum emptied, sometimes giving rise to a question of hernia. If, on the other hand, the hydrocele is of the acquired type, the sac is closed, does not communicate with the abdomen, and cannot be emptied; upon examination with the fingers, the abdominal rings can be distinctly felt; the testicle in these cases, lying at the posterior portion of the sac and a little high up near the ring, can be readily detected, provided the sac is not excessively distended, but even then a careful examination will never fail to discover it unless the testis be absent or retained (as is sometimes the case) in the inguinal canal or abdominal cavity. The scrotum is seldom, if ever, inflamed.

Hydrocele of the cord gives rise to an elastic, painless swelling, of varying shape, from circular to spindle-shaped, and fluctuates on palpation. It is irreducible unless there be a communication with the abdominal cavity. In this case the fluid can be pressed out of the sac, but returns immediately on the patient's coughing, making forced expiration, or assuming the erect position. This form of hydrocele may also be complicated with hernia or with a tumor, from the former of which it is distinguished by its translucency, its greater sensation of fluctuation, and the absence of gurgling; from the latter, by the absence of the firmness and opacity which are usually present with tumors. Of course in these cases due attention will be paid to the possibility of the tumor being a retained testis, and, should the testis be in the scrotum, if any question as to the character of the swelling still exist, an exploratory puncture may be made. Multilocular cysts of the cord are of very rare occurrence in infants and young children.

Prognosis and Treatment.—The prognosis in hydrocele of both testis and cord is usually good, especially in the congenital variety, which tends to self-cure more frequently than the acquired. A good rule to observe in these cases, whether congenital or acquired, is to delay operation as long as possible. Sometimes a communicating hydrocele may be hastened towards recovery by the wearing of a light truss, which excites inflammation and closes the canal. If operative procedures are deemed necessary (and this is more particularly the case in the acquired type), various methods may be employed,—to wit:

Painting the scrotum with a weak solution of iodine in collodion, or with a dilute solution of nitrate of silver in collodion, or with Goulard's lotion, or with alcohol and collodion, or with the iodide-of-lead ointment, in order to excite absorption of the fluid. These local applications are seldom of much use, except when the exudation is very slight.

Acupuncture.—This may be done by puncturing the sac with the needle, evacuating the fluid, and painting the scrotum with collodion to exercise some compression (this latter is not always necessary); or the sac may be punctured with a trocar, and a weak solution of iodine, tincture of iron, chloroform, or alcohol injected into it. A seton passed through the sac is sometimes of service. Finally, a free incision into the scrotum, if carefully made, with due antiseptic precautions and strict attention to cleanliness, is usually successful, even after all the preceding measures have failed. Electro-cautery or opening into the sac by caustics is of little advantage, and is much more severe than the other methods advised.

HÆMATOCELE is simply an infusion of blood into the sac from an injury or from rupture of a vessel, and is exceedingly rare in infants and children. Its causes are nearly always due to some local hurt, such as a blow or severe compression.

Treatment.—The treatment is at first expectant, in the shape of cold applications and painting the scrotum with collodion. If, however, the hemorrhage has been very abundant, it is better to open the sac at once, clean out the clot, tie up any vessels which may have caused the hemorrhage, and allow the parts to heal, which they will usually do with great rapidity.

RETAINED TESTIS.

It sometimes happens that the testicles do not descend from the abdominal cavity, which condition is called cryptorchism where both testes are retained, and monorchism where only one is absent from the scrotum. These organs leave the abdominal cavity, but, instead of dropping into the scrotum where they belong, one may lodge in the anterior wall of the abdomen, in the femoral canal, or in the perineum. This displacement is known as ectopia testis, and is divided into the abdominal, crural, and perineal varieties. Sometimes the testes are congenitally absent, and again it may happen that these organs are not only retained in the abdomen but also united in the median line with the kidneys and suprarenal capsules, while the spermatic vessels, vasa deferentia, and vesiculæ seminales are normally situated, as occurred in a case mentioned by Geoffroy St.-Hilaire,[1] where the patient was considered to be a girl and lived for eighteen months.

Retention of the testes, whether partial or complete, is not uncommon in children, especially during early infantile life, but the testes usually descend by themselves if not too much interfered with. Ectopia is of quite rare occurrence.

Symptoms.—Examination of the scrotum usually reveals the absence of one or both testes, but on passing the finger up the inguinal canal these organs can generally be detected. Coughing, forced expiration, and the erect posture cause the testis to descend on the point of the finger placed in the inguinal canal. Usually examination excites no pain unless pressure be made on the testis.

If the testicle is caught in the inguinal canal, the child complains of pain when sitting, standing, or crossing its legs; and, on examination, the scrotum is found partially or completely empty, and the testes are felt in the inguinal canal. The absence of these organs from the scrotum should always prevent the surgeon from mistaking a retained testicle for a hernia.

---

[1] Histoire des Anomalies de l'Organisme, tome i.

In ectopia testis the organ is usually felt in the abdominal wall, in the groin, or in the perineum, according to its position, and the diagnosis, of course, is comparatively easy.

Course.—The course of the disease is generally favorable, as the testicle usually descends of itself, but sometimes it happens that it does not, when if it is lodged in the inguinal canal it may become atrophied. In cases where the descent does not occur within the first year of infantile life, it is usually associated, when it does come down, with a congenital hernia. Adhesions may also occur between the testis and circumjacent parts, particularly when it is lodged in the inguinal canal, and in such cases the result is a fibrous or fatty degeneration of the organ. Sometimes it is attacked with inflammation ending in suppuration, when the testis, of course, is lost.

Causes.—The causes which induce retention of the testis are due sometimes to an arrest of development, and sometimes to mechanical hinderance to its descent. Small and narrow abdominal rings, premature closure of the canal, non-communication between the scrotum and the abdominal cavity, shortness of the vas deferens, marked hypospadias or epispadias, with ectopia vesicæ and various forms of hermaphrodism, may be enumerated among the causes. In one case mentioned by Birch-Hirschfeld the retention was caused by the right kidney blocking up the inner opening of the inguinal canal, and Hunter speaks of hypertrophy of the testis as being an obstacle in another case. An abnormally enlarged epididymis and an abnormal formation of the mesorchium are also enumerated as causes. Kocher mentions a congenital displacement forward of the large intestine as an obstacle to the descent of the testicle. Retention can also be caused by a lack of proper apposition of the testis in its relation to the inguinal canal, and by a defective development of the cremaster muscle during fœtal life.

The causes of ectopia testis are somewhat obscure. It is said to be congenital, especially the perineal variety, and to be due sometimes to an insertion of the gubernaculum testis in the wrong place, sometimes to an arrest of development in the affected half of the scrotum, and occasionally to traumatism.

Treatment.—In the majority of cases, and particularly in early life, expectancy should be the rule and surgical interference the exception. If the testis is lodged in the inguinal canal close to and protruding from the external ring, gentle traction may be adopted in order to facilitate the descent of the organ, which with a little assistance is sometimes rapidly completed. If the retention is due to a disproportion in size between the inguinal opening and the testis, gentle traction from behind the latter may sometimes assist it through the ring, and sometimes it may be necessary to enlarge the inguinal opening by a subcutaneous incision. Of course, in cases where non-descent is due to a short cord nothing can be done, and, provided it gives rise to no disturbance, the case may be left to itself. If due to adhesions within the abdomen, operative procedure is hardly admissible; but if due to adhesions in the inguinal canal, an incision may be made through the upper part of the scrotum to the inguinal canal, the adhesions broken up, and the descent of the testis facilitated. Where fibrous, purulent, or fatty degeneration has occurred, the testis had better be left *in situ*, unless inconvenience or pain is experienced, in which case the testis had better be removed.

In cases of ectopia testis an operation will very often remedy the difficulty and the organ may be restored to its normal position in the scrotum.

A curious affection of the testes, to which attention was called by St.-Germain in the *Journal de Médecine et de Chirurgie pratique* for 1879, is said sometimes to occur in children in consequence of a severe fright or a blow. He has called it "Réascension du Testicule," and gives two cases in children where, after a blow attended with severe fright, both testicles suddenly disappeared in the abdominal cavity and remained there for a considerable time, in one instance during two months and a half. In both cases he practised gentle traction upon the cord, which was followed by a cure, the testicles reappearing in their proper places.

TUMORS OF THE TESTICLE.

PERIORCHITIS.—Periorchitis, or inflammation of the tunica vaginalis, is not a common affection in children, but is occasionally seen as the commencement of a hydrocele. The serous kind is generally divided into the acute and the chronic variety, but the dividing line between the two is not clear, as the former rapidly merges into the latter. The division which has been made into periorchitis plastica and suppurativa of the acute variety, and periorchitis adhesiva, prolifera, and hæmorrhagica of the chronic variety, is, to my mind, rather fantastic, inasmuch as they are really different stages of the acute or the chronic kind. Periorchitis is sometimes also associated with orchitis or epididymitis.

Symptoms.—Acute periorchitis often begins with a smart fever, accompanied by severe pain in the affected part, which extends over the spermatic cord. The scrotum is red, œdematous, and tender to the touch. The tumor is tense, fluctuating, and non-translucent, and of oval form or flattened sideways. If, as is not infrequently the case, it goes on to suppuration, the fever increases, accompanied by chills, the skin of the affected part becomes red, œdematous, and exquisitely tender, and the swelling either opens spontaneously or is artificially incised.

Course.—Serous periorchitis may end in resolution, leaving behind some thickening of the cord from plastic exudation. The suppurative kind nearly always requires to be opened and treated like an ordinary abscess. Sometimes, however, the inflammation runs a very acute course, extends along the cord, and may induce peritonitis with a fatal termination; but, as a general rule, the prognosis is favorable.

Treatment.—During the acute stage absolute rest should be enjoined, the cord on the affected side supported, and cold evaporating lotions used. On the subsidence of the pain mild compression may be exercised by painting the part over with collodion, but I decidedly deprecate the use of strapping with adhesive plaster, as it not infrequently leads to atrophy of the testis and even ulceration and gangrene of the scrotum. Resolution may be further hastened by local applications of belladonna and mercurial ointment, either alone or in combination,—better the latter. The suppurative variety will need to be opened, when it can be treated like an ordinary abscess by the use of injections into the cavity and the employment of stimulating dressings.

Orchitis and Epididymitis.—These affections of the testicle may be divided into acute and chronic, and are due to inflammation of the testis proper or of the epididymis, or both; and these may still further be divided into the inflammatory, the symptomatic, and the constitutional type.

Symptoms.—Orchitis and epididymitis usually begin with high fever, chills, and swelling, which may attain to a large size. The fever, if very acute, may be complicated with vomiting, abdominal tenderness, and sometimes even a mild attack of peritonitis, particularly if the disease be also complicated with inflammation of the tunica vaginalis. The organ becomes enormously enlarged and is very tender to the touch; the scrotum is red and inflamed, not infrequently there is more or less hydrocele, and the testis is usually drawn up close to the abdominal ring. Under proper treatment this acute condition subsides, leaving behind the chronic variety, which is distinguished by enlargement of the testis or epididymis and thickening of the tunica vaginalis, without much tenderness. If there have been much plastic exudation, adhesions sometimes take place between the tunica vaginalis and the tunica albuginea.

The severity of the symptoms varies very much with the cause of the disease. Thus, if the orchitis or epididymitis be due to syphilis, there is not much pain, but the testis is enlarged, of stony hardness, and under these circumstances is not usually associated with hydrocele.

Causes.—The causes of this affection of the testis are injuries to the organ, urethritis, mumps, possibly an antecedent periorchitis, syphilis, typhus fever, small-pox, scarlet fever, and harsh attempts at catheterism.

Course.—If the orchitis be due to an injury, it usually runs a favorable course, provided suppuration does not occur. The swelling subsides, and the effusion, if serous, is absorbed. If, however, it be complicated with hæmatocele, thickening of the sac generally remains. Cases have been known where a fatal termination ensued in the suppurative kind, from peritonitis and septicæmia.

If it be due to a clap, the swelling and various symptoms subside, but an induration results, especially if the epididymis be attacked. Sometimes, though rarely, atrophy results.

If it be due to syphilis, it ends unfavorably, as atrophy of the organ is nearly certain to occur. If it results from mumps or from the other causes mentioned above, the termination is usually favorable; but it is well to remember that atrophy may be the end of all these affections, although it is not necessarily so. In cases where it is due to injury from the use of a catheter, an abscess, with or without suppuration, may ensue, and in all cases where pus forms, the termination is usually in one of four ways,—to wit, resolution, fungus of the testicle, evacuation of the contents of the tunica albuginea, leaving the shell of the testis behind, or a more or less complete atrophy.

Treatment.—The treatment consists in rest, support of the testis, the application of heat or cold, as may be most agreeable,—the former is, to my mind, preferable,—leeches to the ring and to the inner sides of the thighs, puncture of the inflamed and swollen covering with an ordinary surgical needle, and the subsequent application locally of mercurial and belladonna plasters. In syphilitic orchitis the applications, leeches, and punctures may be omitted, and the patient should be treated by the internal and local administration of mercury and the administration of iodide of potassium by the mouth. In case of abscess of the testis the parts should be incised as soon as fluctuation is detected.

NEW FORMATIONS IN THE TESTIS.—Neoplasms of the testicle may be divided into those of tubercular, syphilitic, cancerous, sarcomatous, and chondromatous origin, fungus of the testicle, and cysts.

Tubercle.—Tubercle of the testicle appears as hard irregular- or oval-shaped nodules, which either undergo caseous degeneration or break down and suppurate. They may sometimes be mistaken for circumscribed gummata or carcinoma of the testis; but they differ from both of these by being attended with pain, inflammation, and fever, by the recurrence of the attacks, and by the absence of other symptoms, whether of syphilis or carcinoma. If the nodules suppurate, the abscesses may be either single or multiple, and, whether of one or the other variety, should be opened only after all methods looking towards absorption have failed. It is not a very common affection in children.

Syphilis.—This may be of the diffused or the circumscribed variety, but usually is of the former. It is of slow growth, and accompanied by other symptoms of syphilis which will assist oftentimes materially in the diagnosis. It may be either of the hereditary or the acquired type. If of the former, the child nearly always dies, not from the affection of the testicle, but from the depression consequent upon syphilis. The acquired variety nearly always terminates favorably (except so far as atrophy is concerned) under a proper treatment with mercury, either alone or in combination with iodide of potassium.

Cancer.—Cancer of the testicle may occur under three forms,—the medullary, which is the most common in early infancy and before puberty, the sarcomatous, the next most common kind before puberty, and the carcinomatous, the most usual after puberty. The encephaloid variety has also been seen in children aged one, three, and five years.

This affection of the testis is usually not attended with much pain or inflammation, but the organ is enormously enlarged, bosselated, and its growth is generally slow.

The circumscribed variety of syphilitic testis may sometimes simulate a carcinoma of the testis, but the absence or presence of other symptoms of syphilis is usually sufficient to enable a differential diagnosis to be easily made. The cancerous testicle is usually oval in shape, but it may be irregular, and is frequently associated with infiltration of the glands in the groin and probably also of those in the abdominal cavity. The cancerous cachexia is frequently present in these cases, and the patient usually dies either from exhaustion incident to the breaking down and suppuration of the diseased testicle, or from cancerous deposits elsewhere. Removal of the testicle is sometimes done, in the hope of checking the disease, but the termination in these cases is generally fatal.

Sarcoma.—Sarcoma occurs during early infant life, and is divided into the two varieties of simple and medullary. It usually develops under the same conditions as carcinoma, runs a rapid course, and in some cases is attended from the commencement with severe pain in the organ, while in other cases the course is painless. It sometimes attains to quite a large size; it is not so fatal as the former variety, inasmuch as castration will sometimes arrest the course of the disease.

Chondroma.—Chondroma of the testis in infants and children is exceedingly rare. I believe that only one case has been reported,—the one of O. Weber's mentioned by Bökai in Gerhardt's *Handbuch der Kinderkrankheiten*, where it occurred as a congenital tumor and was at birth as large as a pigeon's egg, increasing in fifteen months to the size of a goose's egg. This neoplasm was made up principally of cartilage, and was generally hard and nodulated, with here and there points of softening. This enchondroma probably had its starting-point in the rete testis. In this infant there was found within the albuginea a broken-down spot which was filled with a matter resembling thick pus and which consisted of cartilage-cells undergoing fatty degeneration. Enchondroma of the testis is classed among the malignant diseases.

Benign Fungus.—Benign fungus usually commences as the result of inflammatory action, ending in suppuration either of the acute or the chronic variety, or of a tubercular nodule, and frequently implicates the scrotum. After the evacuation of the contents of the abscess, exuberant granulations spring up above the surface of the skin. If the fungus be of the simple variety, the granulations may be destroyed by the knife, by applications of the mineral acids and treatment of the resulting cavity with stimulant applications, and by the administration internally of tonics. If due to tubercle of the testis, removal of that organ is the simplest and best method after all other means have failed.

Cysts.—The curious neoplasms known under the name of dermoid cysts are nearly always of fœtal origin and are considered to be congenital. They may be single or multiple, and, in either case, contain hair, teeth, bones, muscular fibres, nerve-tissue, and sometimes even the greater portion of a fœtal skeleton. An interesting paper upon this subject is given by W. Macewen in the *Glasgow Medical and Surgical Journal* for 1878.

BALANITIS.

Balanitis in infants and young children is a common affection, and may be divided into balanitis of the foreskin and balanitis of the glans penis. Where the latter only is attacked it is, properly speaking, a balanitis, and where it is associated with inflammation of the inner lamella of the foreskin it is known as balano-posthitis. Balano-posthitis, for I shall consider the two affections together, may be divided into the catarrhal, phlegmonous, croupous, diphtheritic, gangrenous, and exanthematous varieties, the most frequent of these being the first, or catarrhal variety. This occurs in the form of superficial inflammation of the mucous membrane lining the glans penis and the inner layer of the foreskin, and may be either general or circumscribed. If the inflammation be of a subacute character, the symptoms extend no farther than the mucous membrane; but if acute symptoms be prominent, then the skin of the genitals participates in the general inflammation, and the disease becomes a dermatitis as well as a balano-posthitis.

Symptoms.—Simple balano-posthitis usually commences with swelling and redness of the foreskin, with eversion of its mucous lining if phimosis be present, and is attended with much difficulty and pain to the child if retraction be attempted. In the earlier stages of the disease there is no discharge, however. If retraction can be made, the mucous membrane is found to be injected, of a deep red or purple color, and if there be any secretion, superficial erosions of the mucous lining of both foreskin and glans penis are found. After a short time, a purulent discharge can be pressed from beneath the foreskin, and this discharge is usually acrid and capable of producing much irritation, not only of the external covering of the genitals, but also of the skin of the inner portion of the thigh and of the groins. The sexual parts then become enormously swollen, and not infrequently the deep purple hue seems to threaten approaching gangrene. The secretion thus expressed commences as a thin, sticky, slightly yellow discharge, which upon exposure to the air rapidly dries and glues together the meatus and the free border of the foreskin. In older children this discharge becomes abundant and may readily be mistaken for a urethritis, especially as from the swollen condition of the foreskin it is impossible to examine the meatus and the anterior portion of the urethra. Of course such cases, both in infants and in grown children, may be associated with a urethritis; and where the urethritis is the real cause, a balano-posthitis may be induced from want of cleanliness or from lack of proper attention and treatment.

Causes.—This variety of balanitis is in the large proportion of cases due to a want of cleanliness. The retention of the smegma or of the last few drops of urine in such children as have an elongated foreskin—and this is the case in the vast majority of children—induces decomposition of the secretion and inflammation of the mucous membrane, with denudation of its epithelial coat. Other causes are improper handling of the genitals by the child's attendant, attrition of the penis against the clothing, and localized irritation of the parts such as exists in eczema of the genitals and of the foreskin, concealed chancroids, and the initial lesion or other manifestations of syphilis. Among older children masturbation perhaps plays some part, but it is not by any means clear to my mind whether the masturbation, which both infants and children affected with a superficial balano-posthitis often practise, may not have been induced by irritation from the disease rather than that the balano-posthitis was produced by the masturbation. Besides these causes, rectal irritation from the presence of ascarides is supposed to induce irritation of the foreskin and external genitals, especially in grown-up children, and in some instances cretaceous deposits beneath the foreskin.

Course.—The course of a simple balano-posthitis is usually of short duration, provided the parts be kept clean and dry. The surgeon should seek as early as possible to find out the cause of the balano-posthitis, whether it is due to local or more distant and remote irritation, such as the presence of intestinal worms or self-abuse. In all of these cases the removal of the cause produces a rapid cure.

Treatment.—The treatment of this affection is in the majority of cases simple, and consists in keeping the parts scrupulously clean and dry. In children, where the foreskin is much swollen, red, and œdematous, frequent douching of the genitals with hot water and painting the external surface of the prepuce with a weak solution of nitrate of silver (from five to ten grains to the ounce), together with subpreputial injections of warm astringent solutions, will be found most effective. As soon as the foreskin can be retracted, concealed ulcerations should be looked for, and if they be of simple character, these also should be touched with a mild solution of nitrate of silver. If these ulcerations, however, are found to be chancroidal, or due to the presence of an initial lesion, the treatment will be different from that which would be instituted in cases of balanitis from simple causes. The chancroid should be thoroughly destroyed as rapidly as possible with some caustic, such as nitric, carbolic, or sulphuric acid, and the parts dressed with iodoform in combination with some inert powder, such as lycopodium, bismuth, or finely-powdered starch. The initial lesion should never be cauterized, provided it be unattended with inflammation, but had best be treated with powdered calomel, either alone or in combination with some of the above-mentioned powders.

The subsequent treatment in cases of simple balano-posthitis is to my mind better dry than wet,—that is to say, by the use of absorbent powders rather than by liquid applications. Wet dressings tend to macerate the parts, to cause a water-soaked condition of the mucous membrane, and to retard recovery. For that reason I seldom use the astringent solutions so often advised for that purpose, but dust the parts freely with iodoform mixed in varying proportions with bismuth, tannin, calamine, powdered starch, and even calomel. Objection may be made to the odor of iodoform, but if the iodoform be mixed with finely-powdered coffee, either with or without charcoal, this objection will be obviated. The blackening effect of the charcoal may be diminished by the admixture of not more than ten per cent. of charcoal to the other ingredients.[1] Before making the dry applications, or even during their use, if the mucous membrane be still much irritated and inflamed, occasional applications of a five- to ten-grain solution of nitrate of silver will be found of much service. If the parts be well dusted, lint or absorbent cotton between the folds of the mucous membrane may be dispensed with, and in my opinion with advantage, as they tend to heat and oftentimes irritate the parts. As soon as the acute inflammation subsides, circumcision should be performed, unless contra-indicated by the presence of chancroids.

PHLEGMONOUS BALANO-POSTHITIS is not a common affection, but it sometimes occurs as the result of a high degree of inflammation, and is not infrequently associated with the variety I have just described.

Symptoms.—The first symptoms are similar to those of the catarrhal variety, except that the redness, swelling, and pain are much intensified. Later in the course of the disease, one, very rarely two or more, small, hard points of thickening are felt in the foreskin, and the skin surrounding them becomes almost erysipelatous in hue. As the inflammation extends, the pain oftentimes becomes severe, the phimosis complete, and micturition painful. This condition of affairs may go on until the abscess is opened or until gangrene is induced from interference with the natural nutrition of the part. All movements of the body and pressure of the clothes, both of the body and of the bed, induce exquisite pain.

Causes.—The causes of this variety of balano-posthitis are partly local and partly general. The catarrhal variety may become phlegmonous, if irritated by masturbation, by injuries, by too severe cauterization in the process of treatment, or by improper and violent attempts to retract the swollen foreskin. A concomitant acute urethritis will oftentimes induce phlegmonous balano-posthitis, and in those cases the phlegmonous inflammation of the part may not only extend to the foreskin but may also invade the sheath of the penis, and even attack the scrotum. The same is true of concealed chancroids beneath the foreskin ; but the initial lesion, on the other hand, seldom gives rise to any acute inflammatory disturbance of this nature. The course of this variety is longer than that of the simple inflammatory type, usually lasting for several weeks, until the abscess either breaks or is opened artificially.

Treatment.—The treatment varies according to the cause. If due to simple abscess, the attempt should be made to abort it by local fomentations in hot water, subpreputial injections, as advised for the simple type, and inunction to the swollen parts of belladonna and mercurial ointments. If such measures fail to produce the desired effect in a few days, and it is evident that the disease is going on to the formation of pus, as soon as the slightest fluctuation can be detected the abscess should be opened, cleansed, and weak solutions of nitrate of silver applied to the wound. The subsequent dressings should consist of the powders already mentioned, when the parts usually will heal rapidly and the concomitant inflammation will subside. If, however, these abscesses are due to the presence of concealed chancroids, the abortive method very seldom succeeds, the disease goes on to suppuration, and the resulting wound becomes chancroidal, either from absorption of or direct contamination by the chancroidal matter. In these instances, incisions should be made as soon as fluctuation is detected, the cavity of the abscess cauterized, and the wound treated as though it were a chancroid, which in reality it is. If the abscess threatens to produce a complete phimosis, and if micturition be seriously interfered with, the prepuce should be laid open by the bilateral method of incision, which will permit of free retraction of the foreskin, and the parts dressed as above advised. As soon as possible the resulting dog's-ears should be removed by the operation for circumcision.

---

[1] A new chemical, called aristol, said to be a di-thymol di-iodide, and to contain a large percentage of iodine, promises to supplant iodoform in the treatment of diseases where this drug has been used, being, it is claimed, free from the pungent smell so characteristic of iodoform.

CROUPOUS BALANO-POSTHITIS in children is a very rare affection. It is characterized by the presence of a whitish, membranous exudation which spreads over the glans penis from the fossa glandis, and sometimes over the inner layer of the prepuce. It is quite superficial, and is attended with but a slight amount of inflammation, and very little, if any, discharge. There is no constitutional disturbance, and the disease seems to be purely localized, yielding readily to treatment, especially to the application of lime-water, either in the form of subpreputial injections or as local dressings. This is one of the few instances in which wet applications answer better than the dry dressings which I have advocated for the more acute inflammatory types. The membrane becomes shrivelled, peels off, and leaves but a slight amount of redness and irritation behind it, and is not attended by local ulcerations or constitutional disturbance.

DIPHTHERITIC BALANO-POSTHITIS is less commonly seen than the preceding variety.

Symptoms.—The symptoms of this variety consist of a swelling of the prepuce, upon which circular or irregular patches of a dirty-gray membrane are seated. These usually occur on the inner lamella of the foreskin, sometimes upon the fossa glandis, and rarely on the glans penis. These patches which extend upon the surface frequently coalesce and are irregular in shape. They cannot be detached, being closely adherent to the mucous membrane, and their outlines are lost in the adjacent necrosing tissues. Sometimes the diphtheritic layer is seated on a wound of the foreskin, and when the bottom of the wound is covered with this membrane the neighboring parts are inflamed and the penis thickened and swollen. Handling excites bleeding of the parts covered with this exudation.

If the course of the disease be towards an unfavorable issue, the swelling of the foreskin increases and the exudation extends over both the inner and the outer layer of the foreskin.

In these diphtheritic cases the concomitant symptoms are much more severe than in the catarrhal or the croupous variety. Thus, erysipelatous swelling of the penis or scrotum, enlargement of the inguinal glands, difficulty in micturition which may go on to retention of urine, and fever, not infrequently occur.

Causes.—The causes of this variety of balano-posthitis are both local and constitutional, but the latter are much more frequently the source of the disease. One of the most frequent of the local causes arises from decomposed smegma or the operation of circumcision, but even then it is extremely doubtful if diphtheria would supervene unless it was dependent upon a constitutional origin, and the so-called scrofulous diathesis is the most usual. It may also follow an attack of scarlet fever, small-pox, or measles. Some low forms of disease in the mother, especially those of an infectious puerperal nature, are said to be a cause of this disease in the child.

Course.—The course of this disease depends upon whether it be due to a local or a constitutional origin. If the former, it is usually rapidly cured, for the diphtheritic patches are, as a rule, small, circumscribed, and are exfoliated, leaving a very superficial ulceration behind, which heals quickly. If due to constitutional causes, the course of the disease is usually a grave one. When the membrane is cast off the resulting ulceration is generally deep, and is again oftentimes covered with a new membrane, causing the necrosis of tissues to extend and even threatening gangrene in its course. Severe deformities may result.

Treatment.—The treatment is twofold,—local and constitutional. The former is most efficacious when the disease is light, the latter when it is severe, although in neither case can constitutional treatment be entirely overlooked. The best local applications in mild cases of the disease are of lime-water, weak solutions of the bichloride of mercury, and dilute carbolized lotions; for the severe cases, washes of the mineral acids, nitric or nitro-muriatic or sulphuric acid in the proportion of from a half to a full drachm to the pint of water. I do not think well of the application of nitrate of silver, except in mild cases, and then only as a stimulant after the membrane has been shed. Of course, in all cases the most scrupulous cleanliness must be observed. If phimosis be present, subpreputial injections of the mild solutions above mentioned should be used, but in cases where the disease threatens to extend, or where serious destruction is imminent, the foreskin should be split bilaterally, even though the edges of the wound are certain to become covered with the diphtheritic membrane. After the operation the wound and the diphtheritic portions of the genitals should be dressed with the acid solutions above described. When the ulcer cleans and the diphtheritic layer has been cast off, powders of tannin, iodoform, or sulphate of zinc, mixed with some inert preparation, such as bismuth, charcoal, or starch, should be used. If the ulcerations become indolent or are covered with flabby, exuberant granulations, they may best be stimulated by weak applications of nitrate of silver, five to twenty grains to the ounce. The constitutional treatment must be of a supporting and tonic character, and should include the various preparations of bark, wine, iron, the mineral acids, and cod-liver oil, either iodized or ferrated.

GANGRENOUS BALANO-POSTHITIS is, strictly speaking, a variety of the other kinds, more commonly of the phlegmonous or the diphtheritic, and is due principally to an interference with the nutrition of the part.

Symptoms.—In the course of a phlegmonous balanitis where the inflammation is very acute, one or more points of a purple hue appear. This discoloration gradually extends until the limit of the interference of circulation is reached. This necrosis of the tissues, in cases where phimosis is a complication, is attended with a discharge of ichorous and fetid pus, mixed with shreds of sloughing tissue; the skin covering the glans penis becomes thin, ulcerates, and the glans penis protrudes through the slough. In this variety the glans penis seldom participates in the gangrene. The sphacelus generally tends to self-limitation, unless it is consequent or attendant upon a diphtheritic balanitis, when it usually extends with the diphtheritic exudation.

Gangrene may also follow in the course of a paraphimosis, when the glans cannot be returned, or from neglect to cut the constricting ring of mucous membrane. In these cases serious deformity from sloughing of the glans penis may ensue. In other cases, as a rule, no deformity results.

Causes.—The causes, as I have already stated, are due generally to some impediment to the circulation, but they are sometimes consequent upon constitutional disturbances, such as scrofulosis, scarlet fever, small-pox, or as the result of an injury. It has been stated that gangrenous balanitis may occur idiopathically.

Course.—The course of the disease depends upon its cause. If from disturbance of nutrition, as soon as this is relieved the gangrene may sometimes be checked. In phlegmonous inflammation it is sometimes extensive, but even in these cases its tendency is towards self-limitation. In diphtheritic cases it is much more serious, because the sphacelus spreads with the extension of the exudation and the gangrene often is deep and severe.

Treatment.—When paraphimosis is the cause of the disease an attempt at reduction should be made, either manually or by incision. As far as is possible the extent of the gangrene should be limited by the employment of all means which tend to restore the proper circulation of the parts, such as hot fomentations, warm local baths, poultices with charcoal, and painting the inflamed tissues with nitrate of silver or tincture of iodine. If the disease be associated with phimosis, it is well to split the prepuce, and this may be done with impunity, as there is no danger of the inoculation of the wound. Subsequent circumcision should be practised after the disease has disappeared. Other local means, such as the subpreputial injections and local applications of lime-water, astringent solutions, carbolized washes, iodoform, or charcoal powders, may be used, together with the internal administration of tonic and roborant medicines.

EXANTHEMATOUS BALANITIS is due to injuries, either accidental or self-inflicted, which induce erysipelatous swelling and inflammation of the parts.

Course.—Its course is usually rapid: the erysipelas spreads, and, if extensive, may become dangerous by inducing constitutional disturbances. As a rule, there is very little discharge with this form of balanitis.

Treatment.—The local treatment in such cases is to check as speedily as possible the spread of the erysipelas with iodine or nitrate of silver applications. Subsequently hot fomentations or lead and opium lotions may be used. The internal treatment should be by the administration of iron in large doses, quinine, the mineral acids, cod-liver oil, and wine, or other stimulants.

URETHRITIS.

Urethritis may occur in children and infants of all ages, and is divisible into two groups,—viz., those which are due to infection from impure contact and those which are due to non-venereal causes. In young infants the first variety is not common, but it is not at all rare among boys at or about the age of puberty. It may be divided into the three varieties of catarrhal urethritis, croupous urethritis, and urethritis of the external orifice or at the meatus.

CATARRHAL URETHRITIS commences with a sensation of tickling and pain during micturition, which speedily becomes quite severe and leads to a desire to pass water frequently. In the earlier stages it is associated with a thin mucous or muco-serous discharge, which rapidly becomes purulent and abundant. In cases where phimosis is present, the discharge produces irritation and inflammation of the mucous membrane of the foreskin and of the glans penis, and may lead to an attack of balanitis, which tends to obscure the true nature of the disease. The disease, at first situated in the anterior portion of the canal, rapidly invades the deeper parts and extends to the prostate gland and the neck of the bladder, producing prostatitis and cystic inflammation, precisely as it may in the case of adults. Epididymitis is also one of the complications which occur with this variety of disease. The urethral mucous membrane is red and swollen and evinces all the symptoms of an acute inflammation. In other words, it is a clap.

The variety of catarrhal urethritis which occurs in infants if due to improper attempts upon the child, runs the same course as it does in cases where impure coitus has been practised. But it must be remembered that all cases of urethral discharge in infants, even when catarrhal, do not necessarily mean impure or improper attempts upon the child's chastity. Intestinal worms, stone in the bladder, a tight and adherent foreskin, and, it is said, masturbation, may induce urethral discharges which closely simulate a clap.

Course.—The course of this variety of urethritis is usually a favorable one, generally disappearing in two or three weeks' time, although it may, in rare instances, last longer. In infants it is not generally attended with any complications of the genito-urinary apparatus, although in boys it may be followed during the later stages by epididymitis or cystitis. Very rarely indeed is stricture the result of a urethritis in children.

Causes.—The causes which induce this disease have already been stated as due either to venereal contact or to masturbation. In addition to these it has been stated in the case of infants to occur idiopathically after vaccination, as well as from local irritation caused by the attrition of the clothing, by the use of catheters, and by the passage in the urine of gravel or small concretions of urinary salts. It has been believed that balanitis may induce a urethritis, but upon this point I am by no means convinced. It has also been asserted that exanthematous affections of the genitals, in which there is much itching and scratching of the parts, may give rise to urethritis.

Treatment.—The treatment of urethritis during the acute stage, when micturition is difficult and painful, when the mucous membrane is highly irritated and inflamed, and before the discharge has fairly commenced, is both local and internal. The local treatment consists of warm fomentations to the part, frequently repeated, to relieve the inflammation, but not poultices, and the application of cold compresses. Internally the administration of a few drops of the balsam of copaiba, the yellow oil of sandalwood administered in milk, or some mucilaginous or syrupy compound will be found, I think, of more service than the use of alkaline mixtures or the various remedies which are employed with the idea of neutralizing the acidity of the urine.

When the acute symptoms have passed away, mild astringent injections may be used, such as zinc, either the sulphate or acetate, alum, tannin, or red wine. With regard to the treatment of the complications, the only one which comes within the province of this paper is the affection of the testis, which has already been considered under the proper head.

THE CROUPOUS VARIETY OF URETHRITIS is an exceedingly rare affection, and one which I have never seen. It is described by Stiebel in "Das Lehrbuch der pathologischen Anatomie," III. Auflage, III. Band, 1861, and Pitha, "Ueber Krankheiten der männlichen Genitalien und der Blase."

It begins with urinary disturbances, retention, and pain in the region of the bladder which extends up as far as the kidneys. The urine, when passed, comes away in drops. The disease is attended in some cases with fever, a small, frequent, hard pulse, dry tongue, constipation, and with pain about the meatus. After the application of leeches, warm baths, and other antiphlogistic remedies, long cylindrical-shaped mucous casts are passed from the urethra, followed by a copious flow of urine, after which recovery takes place rapidly. This usually happens about the third or fourth day of the attack. What the causes of this variety are I do not myself know, nor have I seen it stated in any work to which I have access.

Urethritis of the External Orifice is confined generally to the meatus and the first half-inch of the urethra, and is characterized by swelling of the glans penis near the urethral orifice, eversion of the mucous membrane at the meatus, and the appearance of grayish or yellowish-gray exudations scattered about the mucous membrane of the anterior half-inch of the urethra. These patches bleed readily upon being handled. The appearance of some of these patches is exceedingly suggestive of superficial chancroids or of mucous patches, for which they may readily be mistaken, but they are not inclined to extend nor to produce ulceration. After these patches of exudation have been cast off, the mucous membrane beneath is found to be intact, and the only result of this variety of urethritis is a contraction of the meatus.

Symptoms.—The symptoms complained of are severe smarting in micturition, which is sometimes so sharp as to prevent the child from emptying its bladder during one micturition. Sometimes the disturbance is severe enough to cause the child to cry out during micturition, which is only done as a last resort and when the bladder has become too full to hold any more urine. Sometimes the micturition induces a slight bleeding from the surfaces of the inflamed mucous membrane. There is usually no purulent discharge with this variety of disease, but the slight secretion from the surface of the patches of exudation sometimes dries and produces temporary closure of the meatus, which is forcibly and painfully separated during the first flow of the urine. As the disease goes on to recovery, micturition becomes impeded by the narrowing of the meatus, which is very readily overcome by a slight incision of the part. During the entire attack there is very seldom any fever or febrile disturbance, and the only other symptom besides the difficulty in micturition is a slight pain over the region of the bladder, from distention of the viscus.

Course.—The course of this disease is nearly always slow and chronic, often lasting for months. Sometimes, but very rarely, it may get well in a few weeks. The inflammation remains stationary and is not attended by any complications. In the majority of cases, as already stated, it ends with the contraction of the meatus, and this orifice loses its usual fissured shape, becomes round and narrow, and imparts to the finger the sensation as though there were a piece of stiff parchment beneath the surface of the mucous membrane. The meatus is sometimes so small that the urine comes out in a thin stream and obliges the child to take a long time to empty its bladder.

Causes.—The causes which induce this peculiar condition of affairs do not seem to be clearly understood. It occurs particularly in boys with a short prepuce or in those in whom the prepuce is naturally retracted. The cases which have been observed have all occurred in Jews, and it is believed that circumcision plays a part in its production, or, at any rate, that this operation acts as a predisposing cause towards the disease. It usually occurs within the first seven years of extra-uterine life, and is very probably fostered by lack of cleanliness, dirt, mechanical irritation of the anterior portion of the canal, and inflammation from chemical causes due to changes of the urine in renal and vesical disease, as well as scrofulosis, rachitis, anæmia, and defective nutrition.

Treatment.—In cases where constitutional disturbances exist, attention should, of course, be paid to tonic methods of treatment, and, in addition to this, local means should be employed in the shape of frequent ablutions of warm water, strict cleanliness, touching the exudations with a weak solution of nitrate of silver, five grains to the ounce, and placing between the inflamed and swollen lips absorbent cotton soaked in astringent solutions, alum, sulphate of zinc, etc. Injections in these cases are of no use, and indeed can very seldom be employed, on account of the swollen and contracted condition of the part. For the resulting stenosis of the meatus an incision should be made, which can be kept open afterwards by dilatation with the small sounds used for dilating the meatus.

MASTURBATION.

Infants as well as children are unfortunately addicted to the practice of self-abuse, and in some instances to a marked degree. The symptoms in infants for which the surgeon is consulted are usually those of a nervous type, consisting either in convulsions during sleep, or else, if the child be more fully grown, of constitutional disturbances in the shape of loss of appetite, debility, and mental hebetude. In infants this habit is often practised during sleep by the little patient crossing his legs over his genitals so as to include them between the thighs and by long-continued friction to induce a species of orgasm, which is followed by clonic spasms, sometimes amounting to opisthotonus, a purple congestion of the face, stertorous respiration, upturning of the eyes so that the whites only are visible, and sometimes foaming at the mouth. The surgeon is often put upon the right track by finding, during his examination, that the penis of the boy is in a state of violent erection. Of course the cause of the convulsions and the other symptoms are at once apparent.

In grown-up children the habit is induced either by the example of their companions or by the teaching of their body attendants, and the symptoms in these cases are somewhat obscure. The child is brought to the surgeon for debility and nervous symptoms, which may range from epileptiform convulsions to chorea, dysphagia, loss of flesh and strength, and mental hebetude, in some cases amounting to idiocy. This, of course, is only in cases where the habit has been frequently repeated and for a long time. The surgeon upon examination in these cases usually finds the penis inflamed and disproportioned in size to the boy's years and stature, and sometimes associated with an œdematous condition of the free border of the prepuce.

Causes.—One of the most common of all causes is a long and dirty foreskin, particularly if it be adherent to the glans penis. Besides this, stone in the bladder, constipation of the bowels, the presence of intestinal worms, and balanitis of a mild form are strong predisposing causes for the habit. In grown-up children the example of their playmates, the teachings of older companions, and the reading of indecent literature also operate as causes.

Treatment.—Where masturbation is due to phimosis the first step towards cure is circumcision, and this simple procedure not infrequently brings about complete recovery. If caused by stone in the bladder, an operation for its removal is the only thing that can be done in the way of treatment. Where due to constipation, the presence of worms, or a balanitis, the removal of these causes is sufficient to effect a cure; but it sometimes happens that in spite of all treatment the boy persists in his habit. The most effective way perhaps of breaking it up is to blister a small portion of the penis, taking care that the skin of the scrotum is not invaded, by painting a narrow ring around this organ with vesicating collodion, so that if any attempt at friction be made the pain obliges the infant or child to desist, and by repeating this vesication the habit may frequently be broken up. If the child is old enough to appreciate the difference between right and wrong, he should be advised as to the dangers which result to his health from a continuance of the habit, and by appeals to his sense of decency and good behavior. This in the majority of cases will, with care and attention on the part of his parents or those in authority, gradually cause him to discontinue the habit. In some cases, however, no means, physical or moral, seem to be of the slightest use, and it is usually in cases associated with some organic defect of the nervous system, either in the shape of epilepsy or in that of gradual paresis inducing idiocy, that all attempts at cure seem to be hopeless. Fortunately, such cases are rare, and it may be said perhaps in consolation that, unless associated with some congenital nervous disorder, patients outgrow the habit and suffer no evil consequences from their foolish indulgence in self-abuse. The reported cases of urethritis and urethral stricture induced by masturbation I regard with profound scepticism.

DISEASES OF THE UTERUS, VAGINA, AND VULVA.

BY JOHN M. KEATING, M.D.

THE external genitals of the female child differ in appearance from those of the adult female principally in the prominence of the labia and the absence of pubic hair. "The large and the minute glands are less active functionally than in mature life, and the entrance to the vagina is less conspicuous and is more or less obscured by the hymen. As Leishman remarks, the conformation suggests the greater importance of the urinary as compared with the genital organs during the developmental period of the body. But it also means that the external genitals, with increased susceptibility to infection during childhood, are more exposed should opportunity for infection arise."[1]

A brief description of the anatomy of the female genital tract and external genitals is necessary before considering the affections of these parts. Such knowledge, besides insuring greater accuracy in diagnosis and more thoroughness in treatment, is especially important in view of the fact that disease occurring during the developmental period is frequently the cause of structural alterations and functional disorders found at maturity.

From a medico-legal stand-point the subject of which this article treats is of the greatest importance. It is undoubtedly a fact that the diseases of the genitals of young girls are not so carefully investigated by the physician as they should be; the result is that the diagnosis is frequently based upon the statement of the mother instead of upon a careful inspection, and to her is intrusted the treatment. A thorough examination should be made of every case, and the mother or care-taker instructed practically in the methods of local treatment.

ANATOMY.

Uterus.—I quote from the article on Anatomy, in the first volume of this work: "Until the approach of puberty this organ exists as an undeveloped rudimentary body placed between the bladder and the rectum in the upper part of the pelvis (see Fig. 29). In the child it is wholly unlike what it becomes in the adult, not only in size, but also in its external and internal configuration. The cervix is longer, thicker, and firmer than that of the body. In truth, there can hardly be said to be any body to the organ in early life, for the arbor vitæ reaches to the top of the uterus, and there is no internal os. The upper portion is generally thinner and more flexible, and may be considered as representing the body. About the time of puberty the uterus undergoes rapid changes and acquires its adult character, the body growing faster than the cervix, together with the development of its appendages. The histology and physiology of this organ have been laboriously studied by numerous investigators, and the result of their views inclines to the belief that the uterus is normally anteflexed."

---

[1] A. F. Currier, Medical News, July 6, 1889.

In adolescence, the mucous membrane of the body of the uterus is thin, composed of ciliated columnar epithelium on a delicate basement-membrane, and presents a punctated appearance, owing to the numerous openings of the glandular follicles which are scattered over its surface; these follicles are lined with non-ciliated, cuboid epithelium. The mucous membrane of the neck is much thicker, and is covered with squamous epithelium, the lower portion of which is furnished with villi; the glands at this part resemble those of the body, secreting a clear, tenacious substance. The Nabothian follicles are probably over-distended glands, having a cyst-like appearance, within the mucous membrane.

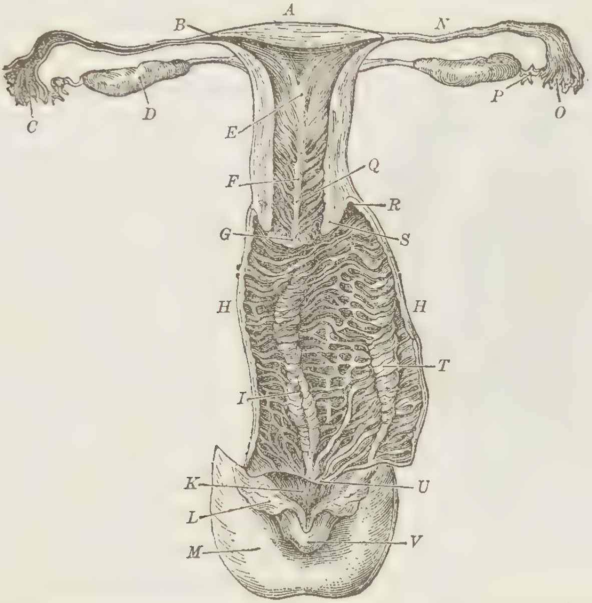
The arteries of the uterus are derived from the uterine artery, a small branch of the epigastric. The veins empty into the uterine plexus, a portion of the blood going to the ovarian veins. The nerves are derived from the inferior hypogastric and spermatic plexuses, and from the third and fourth sacral nerves. The lymphatics run to the pelvic and lumbar glands.

Continuity and contiguity of structure play an important part in the progress of the diseases which have leucorrhœa as a symptom.

The Fallopian tubes or oviducts, measuring about four inches in length, are lined internally with ciliated columnar epithelium, which extends even to the outer or peritoneal surface; in the interstitial portion, or that within the cornu of the uterus, the mucous membrane is entirely smooth, the opening of the tube at this point being very narrow.

Vagina.—The vagina is a tube composed of muscular tissue and mucous membrane, slightly curved from before backward, narrowed below where it joins the vulva, and receiving the cervix uteri at its upper part. Its usual length is two and a half inches in the adult, but it can readily be stretched to twice that length; the walls, as a rule, are in apposition. What are understood as the vaginal columns are two elevations of the mucous membrane, seen anteriorly and posteriorly. Folds or rugæ may be noted running transversely to the longitudinal ridges. (Fig. 1.) These are especially prominent on the anterior surface towards the external outlet. The anterior wall of the vagina is in the vesico-vaginal septum, the posterior in the recto-vaginal septum. By far the most important structure for us to study is the mucous membrane. It has squamous epithelium, which covers large papillæ; the glands of Luschka, racemose glands, are situated at both extremities; throughout the rest of the tube the glands are of little importance.[1]

FIG. 1.



A, uterus; *B*, ostium tubæ uterinæ; *C*, ostium tubæ abdominalis; *D*, ovarium; *E*, cavum uteri; *F*, canalis cervicis; *G*, orificium vaginale; *H*, vagina; *I*, columna plicatus posterior; *K*, vestibulum; *L*, labia minora; *M*, labia majora; *N*, oviductus; *O*, fimbriæ; *P*, fimbria ovarii; *Q*, arbor vitæ; *R*, fornix; *S*, portio vaginalis uteri; *T*, columna plicatus anterior; *U*, hymen; *V*, præputium clitoridis. (From C. Heitzmann.)

Vulva.—In this term are included the mons veneris, the labia majora and labia minora, the clitoris, and the glands of Bartholini or vulvo-vaginal glands. These glands are two in number, rounded or reniform in outline, racemose in character, and yellowish red in color. They lie between the cellular tissue of the vaginal wall and the constrictor muscle of the vagina, behind the lower part of the spongy body. The duct passes forward to open between the nymphæ and the hymen or its remains, its orifices being situated in the fossa navicularis, the space between the commissure and the fourchette. These glands, being for lubrication, are less developed in early childhood. (Fig. 2.)

The mucous membrane of the vulva is covered with squamous epithelium, and is pink in color. Around the nymphæ and urethral orifice are numerous simple racemose gland-follicles. The sensitiveness of the mucous membrane is increased by well-developed papillæ, which are extremely abundant in this position. Sebaceous glands are found at the junction of the skin and mucous membrane, at the free end of the clitoris, and on the labia majora. The lymphatics of the vulva are continuous with the internal iliac and the inguinal glands. This close relationship is well illustrated in the simultaneous pathological involvement of the lymphatics of the extremities or of the pelvic organs and those of the vagina. The blood-supply is derived from the internal pudic artery, the more superficial parts being supplied by branches from the external pudic. The venous circulation is maintained through the vaginal plexus, which empties into the obturator veins. The superficial veins empty into the external pudic and into the femoral. The nerves are branches of the ilio-inguinal and genito-crural of the lumbar plexus.

Hymen.—The description of the hymen given by Dr. Henry C. Coe[1] is as clear as any I know of, and the following is taken from it:

"The hymen is a circular or crescentic fold of connective tissue, covered by mucous membrane, which immediately surrounds the orifice of the vagina and forms the lower extremity of that tube. The hymen is almost invariably spoken of as a 'fold of mucous membrane' which partially closes the orifice. Budin proved conclusively that it is anatomically a folding in the entire vaginal wall."[2]

Pozzi[3] believes that it is an outgrowth from the fœtal sinus urogenitalis, and hence that it is really a part of the vulva. He regards the hymen as the analogue of the bulb of the urethra in the male. To quote further from Dr. Coe, "The hymen ordinarily appears as a crescentic fold situated at the posterior part of the introitus. It lies loosely against the posterior vaginal wall 'like a jib bellied by the wind,'[4] and does not assume the appearance of a tense membrane stretched across the orifice unless the thighs are widely abducted so as to separate the sides of the canal. So little obstruction does this variety of hymen offer to the introduction of a foreign body into the vagina that it frequently persists after repeated acts of coitus." This author, after again quoting Budin[1] as stating that in a single year he had found the hymen intact in no less than seventy-five primiparæ who were examined during labor, says, "It is unnecessary to refer to the medico-legal importance of this structure, since it is an accepted fact that neither is its presence an absolute proof of chastity in its possessor, nor, on the other hand, does its rupture imply that sexual intercourse has taken place."

[1] American System of Gynæcology, vol. i. p. 117.

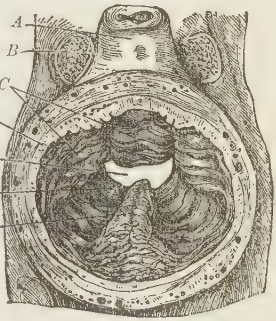
[2] Progrès Médical, Aug., 1879, p. 677; also Ledru, Thèse de Paris, 1855. Dr. Mathews Duncan has seen the hymen present when vagina and uterus were both absent. On these grounds he regarded the view of M. Budin (that the hymen is nothing but the anterior extremity of the vagina) as incorrect.—*Lancet*, Oct. 28, 1882.

[3] Gazette Médicale de Paris, February 23, 1886, p. 86.

[4] American Journal of Obstetrics, January, 1880, vol. xiii.

The hymen is not a thin fold of mucous membrane, as it was formerly believed to be, but it is the lower end of the vagina, and consequently has a variety of shapes. This is readily shown by a section of the vagina in which the external outlet can be seen from within. (Fig. 3.)

FIG. 3.



A, urethra; *B*, corpora cavernosa clitoridis; *C*, columna plicatus anterior; *D*, membrana mucosa; *E*, ostium vaginæ; *F*, hymen semilunaris; *G*, columna plicatus posterior. (From C. Heitzmann.)

I quote from Garrigue,[2] as follows:

Tardieu, who has examined more than six hundred cases with special reference to the hymen, admits five normal conformations, which he places in the following order of decreasing frequency:

1. The hymen consists of a strip of tissue bent at the lower end so as to form two lateral lips, touching one another in a vertical line; which shape is almost constantly found in childhood and sometimes after puberty.[3]

2. The hymen forms an irregularly circular diaphragm, with a more or less large opening in the anterior third (*hymen annularis*).

3. The diaphragm is exactly circular, with a central circular opening (*hymen circularis*).

4. The diaphragm is crescent-shaped, with a concave border turned forward, and two horns ending on the inside of the labia minora (*hymen semilunaris*).

5. The hymen is only represented by a low circular or semilunar edge. This is often overlooked and mistaken for total absence of the hymen, a condition which probably does not exist.

The first successful coitus does not destroy the hymen:[4] it is simply torn, and the flaps can be at once readily approximated and the integrity of the hymen apparently restored. Over-distention (Schroeder) of the vagina by parturition and subsequent involution actually destroy the hymen.

According to Dr. Mundé, physiological lacerations of the hymen are on each side of the posterior commissure, the rent on one side being usually deeper than that on the other. Next in frequency are two rents on one side, one above and one below, and possibly one rent on each side near the upper border of the membrane. The character of these rents after forcible stretching is such that they are apt to unite upon coaptation of the parts.

[3] Courty, Diseases of the Uterus, Ovaries, and Fallopian Tubes.

[4] Mundé, American Journal of Obstetrics, October, 1889, p. 1022.

Atresia of the lower end of the vagina is a well-known cause of hæmatocolpus, hæmatometra, and hæmatosalpinx. Dr. Field[1] has tabulated sixty-five cases of atresia with hæmatosalpinx. In opening the vaginal canal in such cases simple incision will not be satisfactory; according to Dr. Field, a circular piece of the vaginal wall should be removed. Of the sixty-five cases first alluded to, forty-eight died; thirty-nine of these fatal cases had been operated upon. I mention this subject here simply to show the great importance of careful investigation of all cases of delayed menstruation, and also to call attention to the fact that obstruction to a menstrual flow will finally induce uterine hypertrophy and distention of the tubes.

The hymen may exhibit various peculiarities which should be known. The *hymen denticularis* has a serrated instead of a smooth edge; the *hymen fimbriatus* shows a fringed appearance. Then, again, the opening into the vagina may have certain abnormalities. There may be two openings, with an intervening septum. If these openings are round or lengthy and large, it is called a *hymen biforis* or *bifenestratus;* if the septum is large and the openings are small, it is called a *hymen septus.* When its partition does not unite in the middle but grows from the anterior and posterior portions, it is called a *hymen subseptus.* When perforated, it is a *hymen cribriformis.*

I have dwelt at length upon the anatomy of these parts because I am convinced by my reading and experience that sufficient attention has not been paid to the consideration of the affections of the mucous membrane of the genital tract in young females. The catarrhs of infancy—which, as we shall see, may result from cold, pent-up secretions, want of cleanliness, etc. —act upon the mucous lining of the uterus and tubes as they do upon that of the nasal chamber, producing congestion, infiltration, and finally stenosis of the passages. The effect this has upon the uterus is to congest it, to obstruct its canal, and to increase its weight; and undoubtedly the uterine flexions and versions, with their many symptoms, including dysmenorrhœa, that attend puberty or follow it, owe their origin to this cause. "Either vulvitis or vaginitis may exist alone, but more frequently the infectious disease which begins with the vulva does not end there. In adults this disease not infrequently extends to the uterus, the Fallopian tubes, the ovaries, and the peritoneum, and may end fatally. . . . It seems extremely probable that many of the deformed and undeveloped uteri with which are associated so much dysmenorrhœa and anguish, sterility and domestic unhappiness, are the legitimate consequence of vulvo-vaginitis in early life."[2] If it were generally known by mothers that vulvo-vaginal catarrh is a serious matter and needs careful and early attention, many times would the family physician's attention be called to the subject and treatment instituted; as it is, ordinary cases are passed unnoticed, or only a superficial washing is given to insure cleanliness. Every mother should be taught that no child should have protracted leucorrhœa,—that it is always a pathological condition and needs the immediate attention of the physician.

[2] Currier, Medical News, July 6, 1889.

As almost all the affections of the female genital organs are accompanied by a discharge, we will take this symptom into consideration.

LEUCORRHŒA.

Synonymes.—Fluor albus, the Whites, White discharge; French, Leucorrhée; German, Weisser Fluss.

Definition.—A discharge or excessive secretion, non-hemorrhagic in character, coming from any portion of the mucous surface of the female organs of generation.

Etiology.—Leucorrhœa is usually the result of an inflammation of the mucous membrane of the female sexual organs. The conditions which give rise to inflammation may be classified as follows: (1) the simple catarrhal, (2) the infectious, (3) the phlegmonous, and (4) the diphtheritic.

A classification may be made based upon the part of the mucous membrane affected: (1) vulvar or infantile, (2) vaginal, (3) cervical (also common in childhood), (4) intra-uterine, (5) tubal. This division is an arbitrary one, as extension of the inflammation may take place.[1]

The inflammation may be general, and be the result of the strumous diathesis, cold, filth, ascarides (?); it may be local, and limited to the vestibule, the navicular fossa (Figs. 1 and 2), the muciparous follicles and glands, or the glands of Bartholini (common cause of labial abscess),—and be the result of the same causes. The inflammation may be specific, and be due to gonorrhœa, syphilis, erysipelas, noma, or one of the eruptive fevers; or it may be the result of eruptions, as eczema, erythema, herpes, prurigo, or acne. Tumors may be present, such as hypertrophies, hernia, cysts, and new growths. The new growths may be fibromata, sarcomata, carcinomata, or cystomata. Of course all injuries to which these parts may be subjected should also receive careful consideration.

DISEASES OF THE UTERUS.

TUMORS.—An interesting case of malignant adenoma in a girl of seventeen is reported,[2] which was cut away several times, but recurred, and finally formed a large tumor, which caused the patient's death. Rosenstein described a case of cancer of the fundus uteri in a child aged two. In this case a solid tumor reached high above the symphysis, causing dysuria. The inguinal glands were swollen. After death a mass was found projecting from the right side of the fundus, and another from the left side; the latter was softening. Deposits covered the anterior peritoneal surface of the bladder. The uterine mucous membrane, cervix, tubes, ovaries, and vagina were healthy, though under the microscope the tumor appeared in parts of sarcomatous character; in others it was truly cancerous. Eckhardt has noted a case where a large mass which filled the vagina sprang from the cervix of a girl aged nineteen. The growth was apparently rather a sarcoma than a cancer. Gaughofner, after noting the above cases, describes[1] a case where the cancer attacked the vaginal portion of the cervix of a girl aged eight. For two or three years blood kept escaping from the vagina. The growth was fungous and very brittle; it was confined to the anterior part of the cervix, and the vagina was quite free from disease. The tumor was carefully cut away, and its base ("of the size of a twenty-kreutzer piece") cauterized. Under the microscope it proved, according to Professor Chiari, to be a medullary glandular carcinoma. No secondary deposits were found, and no glands were enlarged.[2] Schuata described a case of malignant adenoma of the cervix in a girl aged sixteen; Glätter, in one of seventeen; and Eckhardt, in one of nineteen.[3] The exciting cause in these cases was not definitely determined. It has been noted that this malignant growth is, as a rule, more virulent in young than in older subjects. The treatment may be palliative, but general opinion inclines to the immediate removal of the tumor, if possible, though this is, of course, not permanently curative.

[2] British Medical Journal, January 5, 1889.

DISEASES OF THE VAGINA.

1. Simple Catarrhal Vulvo-Vaginitis.—This is an ordinary catarrh of the mucous membranes, and has all the characteristics that belong to catarrh elsewhere. It is extremely common among the poor and uncleanly, though by no means dependent alone upon dirt and irritation. It is a common accompaniment of malnutrition, and consequently is found usually in cachectic children of all ages. A slight leucorrhœa may be noticed in delicate children, and need not cause alarm, as it will yield readily to tonics and is only an evidence of anæmia. It may also be the forerunner of puberty, and will be found especially in girls of nervous temperament, rapid growth, and early development. There is excessive secretion from the muciparous glands, and also a transudation from the blood-vessels. It can be produced by any outside irritation, or may accompany the eruption of an eruptive fever, especially scarlet fever and variola. The discharge is colorless, and at times very irritating; indeed, often attention is first called to it by the excessive itching it produces. In children the itching causes the patient to rub the parts continuously, and either produces excoriation or leads to masturbation. Frequently, if there is want of cleanliness

---

[2] British Medical Journal, January 5, 1889.

[3] Annual of the Universal Medical Sciences, Sajous.

or excessive local irritation, the discharge dries upon the surface, is mucopurulent, the parts become ulcerated, or crusts form which leave sores when disturbed.

The physician should make a very thorough examination, especially of the vulva, of these cases when brought to him. The introduction of foreign bodies will cause a vulvo-vaginitis, and attempts at rape, even when gonorrhœa can be eliminated, will produce a catarrh through traumatism.

Treatment.—In adolescence leucorrhœa prevails as an accompaniment of the rheumatic and gouty diatheses, during convalescence from various fevers, in pulmonary phthisis, and in local tuberculosis. The treatment, therefore, in all cases has to be either constitutional or local, and in most cases both. In the child as well as in the adult, if the leucorrhœa is indicative of a cervicitis,—that is, if it is composed of a glairy mucus with destroyed endothelial cells (the whites), accompanied by more or less irritation of the parts,—constitutional treatment is most important. Fresh air, generous diet, bathing, massage, iron, arsenic, quinine, cod-liver oil, bichloride of mercury (in minute doses), and red wine are indicated.

Constipation is extremely common in all cases that have leucorrhœa as a symptom. Careful inquiry will frequently prove this though the statement be made that the child has a movement every day: an accumulation of scybala will usually be revealed by a large enema. Attention to this matter should be the initial procedure in every case. Every evening the child should have, if needed, an enema of tepid water with a pinch of salt and a small quantity of olive oil; and each morning, before breakfast, a glass of pure spring water, or a half-teaspoonful of compound liquorice powder, or Tarrant's aperient, or elixir of cascara sagrada, or bitartrate of potassium. A glycerin suppository occasionally is useful. The child should have a morning bath and rapid sponging with salt water (a half-ounce to a gallon) and friction. The genitals should then be anointed with some substance that will not become rancid. My preference is for carbolated white vaseline, or white vaseline and lanoline and oxide of zinc ointment. After this the parts should be dusted with fine boric acid such as is used by aurists. This can be done with a powder-insufflator. If the mother cannot use this, vaginal suppositories can be inserted of iodoform, boric acid, subnitrate of bismuth, acetate of lead, or tannin. If the discharge is annoying, causing much pruritus and quite abundant, a small quantity of glycerole of tannin should be introduced into the vagina in suppository form with oleum theobromæ, and retained by a cotton pad.

The cases that require the treatment just indicated are those ordinarily known as "whites," the simplest form of mild catarrh. In very mild cases, and in older children, washes may be of service, provided they are made to enter the vagina. The simple washing of the external genitals with infusion of white-oak bark or alum-water is seldom of any service in any form of infantile leucorrhœa.

Of course in all these cases constitutional treatment should be instituted:

cod-liver oil, with syrup of hydriodic acid or syrup of iodide of iron, is especially indicated.

2. THE INFECTIOUS VARIETY OF VULVO-VAGINITIS.—Although I believe that most if not all of the cases of vulvo-vaginitis that present the characteristics which accompany this form are gonorrhœal or specific in their origin, I have adopted the title of *infectious*, so as to include the doubtful cases.

The presence of the gonococcus certainly is sufficient at the present day to carry with it a strong supposition of the gonorrhœal origin of the case. Spaeth[1] examined the discharges from twenty-one cases of vulvo-vaginitis in girls between three and eleven years of age, and found Neisser's coccus in fourteen. In none of these cases did the inflammatory process extend to the urethral mucous membrane, whereas in adult females the urethral discharge always contains cocci. The gonococcus may be detected after the method of Neisser. A drop of the secretion is pressed between cover-glasses, dried over a spirit-lamp, stained with methyl-blue, passed through oil of cloves, and mounted in Canada balsam. The gonococci are then readily recognized, even with a one-fourth-inch dry objective and a D eye-piece; for differential study a higher magnifying power is necessary.

The form of vulvo-vaginitis under consideration has its analogue in the ophthalmo-blennorrhœa neonatorum; its highly infectious character is demonstrated by the rapidity with which it attacks children in hospitals and asylums where the little inmates are neglected, where they are washed in the same tub, possibly with the same water, and where the soap and towel are common property. It is often found in children of filthy habits.

Diagnosis.—Possibly attention is not called to the case until it has progressed for some time. The labia are red and swollen, the mucous membrane resembling "wet hemlock sole-leather," the secretion being purulent, muco-purulent, or sanguino-purulent. The discharge has probably excoriated the parts in the vicinity, and has dried in crusts or in the creases. Undoubtedly most, if not all, of these cases are of gonorrhœal origin, and the mucous surfaces most affected are those external to the hymen, including the urethra. Severe urethritis is almost pathognomonic of gonorrhœa, though this is most common in the adult. Should the case have lasted for some time, or if it has been caused by sexual intercourse more or less complete, the inflammation will not be limited to the mucous membrane of the outlet, but will involve the vagina and the cervix and eventually produce a salpingitis. The representation of the mucous membrane in Fig. 2 shows how easily the infectious material can become located in the vaginal folds. In asylum cases, or in children of the poor and dirty, an infectious vulvo-vaginitis is liable to take the same course, and tubal or ovarian disease and even peritonitis may result.[2]

---

[1] München. Med. Wochenschrift, May 28, 1889; also an interesting editorial in the New York Medical Journal for July 13, 1889.

[2] Francis Huber, Archives of Pediatrics, December, 1889, p. 887.

Treatment.—In cases of long-standing leucorrhœa the treatment should consist in first etherizing the patient and making a thorough examination. The surface should be cleansed by irrigation throughout the vaginal tract, and in all cases where applications are required to the mucous membrane of the vagina and uterus they should be made above the line where the mucous membrane seems affected.

Having thoroughly washed out the cavity, the large blade of a Skene's urethral speculum should be used in the Sims position, care being taken not to tear the hymen, and whatever application is necessary should be made at once. The mucous membrane may be wiped over with absorbent cotton, and the vaginal surface then thoroughly coated with a strong solution of nitrate of silver, twenty to thirty grains to the ounce; or we may employ a solution of sulphate of copper, boric acid, carbolic acid, and glycerin, the parts being well greased with a stiff ointment, in order to keep the surfaces thoroughly lubricated and apart.

In cases of the infectious variety the mucous membrane should be thoroughly cauterized with the solid silver stick, or with a strong solution of nitrate of silver, or some of the other materials already mentioned, great care being taken that all diseased portions of the mucous membrane have been reached. If the disease has lasted some time, it will be found that the cervix is also affected, and before a cure can be brought about it will be necessary to make a similar application to this surface; neglect of this is probably the cause of so many cases of leucorrhœa or gonorrhœa existing after the treatment has been supposed to be most thorough. The mucous surfaces should then be kept apart by means of lint or cotton covered with oleaginous material, carbolized oil, or benzoated zinc ointment, and thoroughly irrigated—not merely syringed—with either a hot solution of corrosive chloride of mercury, in the proportion of one to five thousand, or calomel ʒi, listerine ℥i, aquæ calcis ʒv; or the following may be used, diluted to suit the case:

℞ Benzoic acid, gr. xxx;
Oil of wintergreen, gr. lx;
Oil of eucalyptus, gr. lx;
Thymol, gr. c;
Salicin, gr. xl;
Glycerin, f℥ii;
Water, f℥xxii;
Alcohol, f℥xl.
To make O iv.

Injections of red wine are also efficacious, and, if much pain exists, belladonna and opium may be added to the injection.

Should it be found that the disease involves the uterine canal, applications should be made to the entire endometrium, even as far up as the fundus if the internal os is patulous.

The character of the application should depend entirely upon the extent of the inflammation of the mucous membrane. Ordinary simple catarrh, which is superficial, possibly may need only the mildest form of alterative and astringent applications, such as chlorate of potassium, ferric alum, tannin, and the abundant use of hot water to diminish local congestion. The hygroscopic property of glycerin renders it most valuable in relieving congestions of the mucosa. Tampons of cotton or wool impregnated with glycerin should be inserted into the vagina to support the uterus; and astringents, such as tannin, may be incorporated with the glycerin.

Thorough cleanliness should be insisted upon, and, after this has been attended to, the physician may select for himself the wash or application which he prefers. I will offer simply a few suggestions as to treatment, referring to the articles quoted for a more elaborate exposition.

J. B. Johnson,[1] after dwelling upon the highly irritating character of the discharge in vulvo-vaginitis and also the danger of infection, recommends the following:

℞ Acid. carbol., gr. x;
Sodii bibor., ʒii;
Glycerini, ʒi;
Aquæ, f℥v.
Misce.

Shake well, and use four times daily, after the parts have been well washed.

In severe vaginitis he recommends balsam of copaiba, three or four drops, placed in the ostium vaginæ and allowed to remain there. If pure copaiba irritates, mix with equal quantities of cacao butter or carbolized vaseline and apply with a camel's-hair brush.

T. G. Thomas[2] advises that the vagina should be thoroughly cleansed and then a wash used of one ounce of "black wash" to a pint of water.

Ellis[3] advises a thorough washing with warm water, and then a weak astringent lotion of sulphate of zinc, alum, acetate of lead, boric acid, or nitrate of silver, according to the severity of the case. He advises cold salt-water baths with friction with a coarse towel, and change of air to the sea-shore, also ferruginous and bitter tonics.

It is well not to begin treatment with materials that will stain the clothing, but of course, should the discharge persist despite milder applications, nitrate of silver, tannin, etc., will have to be used. In severe cases of vulvo-vaginal catarrh in infants, as well as in older children, it is far better to make a thorough application at once to the mucous surfaces. For this purpose the child should be etherized, the parts well irrigated with warm water and bichloride (one to four thousand) or with creoline, the vagina opened carefully by means of a speculum of the Sims pattern (a bent pewter teaspoon handle serves well), and the whole canal packed with strips of iodoform lint. The orifice of the urethra should be painted with a solution of the nitrate of silver (ten or fifteen grains to the ounce). Iodoform should be sprinkled well on the mucous membrane of the external opening, and the whole vulva covered with a mass of borated absorbent cotton. This outer dressing should be removed when the child urinates, and a fresh one applied. In twenty-four hours the lint can be removed, and the parts well irrigated with Dobell's solution or a lotion of black wash and listerine. Dobell's solution has the following formula:

---

[1] Medical and Surgical Reporter, May 12, 1888.

[2] Ibid., March 31, 1883.

[3] Diseases of Children.

℞ Borate of sodium, grs. 120;
Bicarbonate of sodium, grs. 120;
Carbolic acid, crystallized, grs. 24;
Glycerin, f℥ ½;
Water, enough to make f℥ 16.

Dissolve the salts in about eight fluidounces of water, and add the glycerin and carbolic acid, previously liquefied by warming. Then add the water to make sixteen fluidounces, and lastly filter.

An application of a five-per-cent. solution of cocaine to the parts with a camel's-hair brush will allay pain and smarting and allow the child to permit of the thorough washing necessary.

Should there be the least suspicion of gonorrhœa, no time is to be lost. The vagina must be thoroughly dilated, and a solution of nitrate of silver applied to the whole surface, followed by a dressing consisting of thorough packing with cotton or lint smeared with the oleate of bismuth or the subnitrate of bismuth with glycerin (Currier).

3. PHLEGMONOUS VULVO-VAGINITIS is usually either due to traumatism or may accompany or follow the eruptive fevers. Possibly in children who are otherwise diseased, the irritation of a simple catarrhal vulvo-vaginitis may be productive of ulceration and gangrene. The infectious and phlegmonous types may be associated.

Treatment.—Thorough cleanliness should be enforced, and modern antiseptic measures instituted, preceded, if necessary, by surgical treatment. Frequently, should ulceration and gangrene set in, cauterization will be required. Tonics, stimulants, nourishment, and fresh air are imperatively indicated.

4. DIPHTHERITIC VULVO-VAGINITIS.—This is not confined to cases of diphtheria, but may accompany all septic diseases, including scarlet fever and measles. It is, of course, of very serious import to the life of the patient, and there is great danger of infecting others. It leads to gangrene and septicæmia.

Treatment.—Vulvar and vaginal diphtheria should be treated with the same thoroughness as diphtheria of the air-passages. A solution of salicylic acid has been recommended as a specific by some. A frequent application of peroxide of hydrogen has been advocated by many. The parts should be treated antiseptically, washed, and packed, so that the whole surface shall receive treatment. In diphtheria the complication is apt to be very fatal, as it shows the dyscrasia to be well marked, and the treatment, as far as supporting the system is concerned, must be heroic.

Cysts of the vagina constitute a form of tumor which occurs oftener than is usually supposed, though comparatively rare in the very young. Johnston[1] cites fifty-two cases in which the age of the patients had been noted, and among these five were between the ages of ten and twenty years, and one was under ten years. Neither heredity nor constitutional tendency is considered a predisposing cause, but rather disease or injuries which directly alter the tissue of the vaginal wall. Among the theories which have been advanced are the following:[2]

1. That they are the result of an accumulation of the secreted fluid in a depression formed by the union of the crests of two contiguous folds of mucous membrane.

2. That they are the result of simple dilatation of the lymph-channels which traverse the connective tissue of the vaginal wall.

3. That they owe their origin to the ducts of Gärtner.

4. That they owe their origin to the glands in the vaginal mucous membrane.

They occur as simple, compound, single, and in masses. Usually they appear singly. Their size varies from that of a pea up to that of a pear, though a size about midway between these extremes is oftenest met with. According to Winckel, their location is on the anterior or the posterior wall of the vagina, as a rule, and usually in the lower or the middle third, though Johnston states that they occur more often in the upper part. They are frequently accompanied by a leucorrhœal discharge and a mechanical interference with function. Pain and tenderness occur chiefly where inflammation and irritation exist. Occasionally marked nervous symptoms are present.

Several modes of treatment have been advised in the removal of these growths. Johnston, in the article referred to, inclines to Schroeder's operation if the cyst cannot be cured by puncture or incision. This consists in the removal by scissors of all that part of the growth that projects above the vaginal surface, and the union by sutures of the mucous membrane of the vagina to that which lines the tumor. Enucleation, though safe and advisable in small cysts, becomes dangerous in cysts of larger size.

Fibroma.—This is a rare condition, yet its occurrence in early childhood has been reported.[3] The upper third is usually the region of the vagina which is affected. Its cause is obscure. It may be a congenital growth or it may be developed later, appearing generally about the age of puberty. The symptoms produced are very similar to those of a like condition of the uterus, including the bleeding and discharge. As a rule, removal of the growth, either by ligature or by the knife, is advised, unless contra-indicated by its position, vascularity, or some form of complication.

---

[1] American Journal of Obstetrics, November, 1887.

[2] Dr. J. M. Baldy, Philadelphia Medical and Surgical Reporter, February 15, 1890.

[3] Mann, Gross.

Generally a small tumor should not be disturbed by radical measures. Winckel advises recourse to surgical interference when the tumor has reached the size of a walnut, for then its disturbance of function and its tendency to cause displacement become matters of serious import.

SARCOMA is even more rare than fibroma, yet various cases of its occurrence in early youth are on record.[1] Dr. R. W. Taylor reports[2] cases of melano-sarcoma in adults, and refers to Köbner.[3] Schuchardt, in a paper read before the second congress of the German Gynæcological Society, held at Halle in May, 1888, cites two cases. According to Schubert, of seven cases reported only one was noticed at birth, the ages of the other children ranging from two to five. The etiology of these growths is obscure. Any congenital lesion or any irritation of the parts may be a primary cause. Dr. Schuchardt believes that in the cases coming under his observation the tumors originated from certain papillary structures which normally exist in the region of the vagina. The treatment is removal as soon as possible. In the article referred to above, Dr. Taylor speaks favorably of the action of arsenic injected into the mass. According to statistics, this growth has proved very malignant, metastasis occurring through the vascular system, and after removal the formation being reproduced. The prognosis is then of necessity fatal, and relief of the suffering is all that can be looked for.

CARCINOMA, like sarcoma, is exceedingly rare. Mann cites two cases between fifteen and twenty years, and one case in early childhood. The cause of this formation is the same as that of sarcoma, heredity, however, having a strong influence. Metastasis occurs along the course of the lymph-vessels, and tendency to renewed growth after excision is the inevitable consequence, should the patient survive. Palliative treatment necessarily is to be adopted, and, if feasible, the growth removed as quickly as possible, and, as in all cases of growths or disease of these organs, the patient should be given nourishing food, plenty of fresh air, and tonics, so as to build up the general system.

Foreign bodies introduced into the vagina from without are not of infrequent occurrence, comparatively. They give rise to irritation, and if left long enough produce great pain and discomfort, even going on to ulceration. Removal of the cause and treatment of the parts involved constitute the method of procedure under such circumstances.

DISEASES OF THE VULVA.

PRURITUS VULVÆ.—This is an annoying and very frequent condition, depending in children upon various causes, which may be either local or constitutional, but usually are both. Almost all forms of leucorrhœa will produce irritation of the genitals. The causes may be classified as follows: (1) animal and vegetable parasites (ascarides being most common in young girls); (2) diseases of the vulva; (3) diseases of the urinary system (diabetes, etc.); (4) vaginitis; (5) diseases of the uterus; (6) ovarian and other tumors; (7) skin-affections; (8) diseases of the nervous system.[1]

[1] British Medical Journal, September 6, 1888, and January 19, 1889.

[2] New York Medical Journal, July 6, 1889.

[3] Berlin. Klin. Wochenschr., No. 1, 1881.

Where the history of pruritus vulvæ is presented, of course it is necessary to understand thoroughly the cause, in order to treat it intelligently. It is necessary to inquire into the history of the case and the constitutional tendency of the individual, and the family record should be investigated as to the question of tuberculosis. Careful search should be made for the existence of any parasitic affection, and inquiry instituted as to the presence of vesical and urethral disorders, diabetes, etc. The genital organs should be carefully examined for evidence of leucorrhœa, psoriasis, eczema, or any other local skin-affection.

The absence of pubic hair will preclude the possibility of pediculi, but scolices may find an entrance into the tender tissue of the groin and the neighboring parts.

Treatment.—In regard to treatment, it should be both constitutional and local, the constitutional treatment consisting of proper hygienic measures, assimilable nutriment, tonics, if necessary, and plenty of fresh air. The nervous system requires careful attention; in fact, it may be necessary to employ sedatives for a time, but the use of opium should be avoided. A careful study of local causes should be made, that proper treatment may be instituted. The use of local applications which are sedative to nerve-termini is indicated in all cases of neuropathic origin. Of these, painting with menthol, peppermint, and cocaine is of the greatest value; but when these applications are made, it should be remembered that their favorable action does not last long, and that constant reapplication to the sensory nerve-filaments in the papillary layer of the cutis is necessary. Routh[2] mentions urethral caruncle as a possible cause. This should be borne in mind, and proper treatment instituted, if necessary. In the pruritus from leucorrhœa of vaginitis he advises constant bathing of the part with a solution of—

℞ Borax, teaspoonful;
Oil of peppermint, gtt. v;
Water, hot, Oi.
Shake well, and bathe the parts freely with a soft sponge.

Julien's formula is an excellent local application:[3]

℞ Zinci oxidi, gr. xxv;
Acidi salicylici, gr. i;
Glycerini amyli, gr. xxv.
Apply locally.

[1] Wiltshire, British Medical Journal, March 5, 1881.

[2] British Medical Journal, April 14, 1888.

[3] Journal of Venereal and Cutaneous Diseases, April, 1886.

Ascarides can usually be detected, and thorough washing, with an application afterwards of carbolized oil or vaseline or the use of enemata of olive oil and lime-water, will destroy them. Should the irritation remain, a lotion of black wash and vinum opii will be of service. When the itching is associated with much inflammation of the vulva, it is advisable to employ a demulcent wash, such as infusion of marshmallow, or to apply a poultice of linseed-meal or potato-starch with vinum opii or infusion of poppy-heads, until the inflammation shall have subsided.

For pruritus ani the following will be found beneficial :[1]

℞ Hydrarg. chlor. mit., ʒi;
Balsam. Peruv., ʒiss;
Acidi carbolici, gr. xx;
Lanolini, ℥i.
Once or twice daily.

Condylomata.—It is not necessary to go into a detailed account of this affection, as it is treated of in all works on venereal diseases. It may be stated, however, that it is a very common form of cutaneous growth, which, as a rule, is located in the neighborhood of the anus and the genital organs, and is due to irritation produced by acrid vaginal or rectal discharges. According to Winckel, "sharp or acuminate condylomata arise from a multiplication of papillæ, but occur upon parts devoid of papillæ." They are of frequent occurrence on the labia, and in the vestibule, even extending over the thighs and upon the abdomen. They are usually quite small, but the size varies from that of a millet-seed to that of a walnut and even larger. "They are always pedunculated, generally flat, at first fringed or shaped like a cock's comb, and are much softer than papillomata." They are vascular, and liable to become painful and inflamed if subjected to friction, infecting healthy skin with which they come in contact.

There is some difference of opinion as to the definite cause of these structures,—whether it be gonorrhœal or syphilitic, or whether they may not be spontaneous growths. Fritsch reports cases of children under one year on whom were pointed condylomata where gonorrhœal infection was out of the question. Other instances[2] are reported where children under twelve years of age were so affected, with entire absence of any venereal or constitutional infection.

Acuminated condylomata originating in the papillary layer of the skin of the labia may appear, independently of venereal or constitutional infection, but their presence should undoubtedly be looked upon with suspicion.

The treatment of these growths is chiefly local. Solutions of corrosive sublimate in alcohol and corrosive sublimate and collodion have been highly recommended; but the speediest and most effective method is the use of the knife or of caustic, perfect antisepsis being observed.

---

[1] Progress, Dr. J. M. Mathews.

[2] Dublin Journal of Medical Science, February 2, 1880.

ELEPHANTIASIS OF THE LABIA is certainly a rare disease in this country. I have seen one marked case, which occupied the labia and which corresponded to the usual description, though the history was indefinite. The patient did not improve under various forms of treatment, and finally was lost from observation. This girl was about fourteen years of age. Her general health remained good notwithstanding the annoying character of the affection. Virchow regards the disease as originating in the lymphatic glands. The aspect of the growth is that of an hypertrophied condition of the labia, of irregular, papillary, or cauliflower-like appearance, composed of innumerable cysts, from which there is constant oozing, causing intense irritation. The elephantoid appearance is well marked.

The question in the case mentioned was in regard to the feasibility of an amputation of the labia. Emmet, in the two cases with which he had to deal, adopted this method of treatment.

GANGRENE OF THE LABIA.—This seems to be generally a condition resulting from some previous lesion, either traumatic or some constititutional disturbance, as fevers, measles, and diphtheria, especially measles. It has sometimes been found in connection with embolism and hæmaturia. By some it is held that it is identical with hospital gangrene and noma. Ranke[1] says that different forms of gangrene resulting from noma can unquestionably occur in children who have a tendency to diseases of this kind, and he ascribes its infectious character to the presence of micro-organisms. The disease is inoculable and contagious. After an epidemic of measles in the New York Foundling Asylum in 1874, gangrenous vulvitis occurred in some of those who had been affected (Smith). Occurring on the mucous surface at one or more points, it spreads with great rapidity. The labia are of a dark, livid red, as is also the adjacent mucous membrane. Gangrenous spots appear, enlarging until the part affected is covered with a fetid slough.

Treatment.—Antisepsis as far as possible is one of the first requirements. If the gangrene be of the dry kind, dry, hot applications should be used,—bags of sand or bran. Cold must be avoided. Hot fomentations of boric lint or poultices may be required to stimulate the separation of slough. Chlorate of potassium has been highly praised as a local agent. E. St. George Queely[2] checked ulceration by the free use of solid silver nitrate, and used as an additional application zinc ointment made with vaseline and carbolic acid. Early and thorough cauterization by nitric acid or bromine is often urgently indicated. When the labia are hard and swollen, a deep incision has proved beneficial. Sometimes the actual cautery is of use, and its rapid effect favors the idea of a local cause. Tonics, stimulants, and nutritious food are necessary for constitutional treatment. Some advise the use of quinine in large doses.

---

[1] Jahrbuch für Kinderheilkunde, xxvii. 3.

[2] Lancet, January 12, 1889.

Prompt and active measures should always be employed as soon as the affection presents itself; otherwise the prognosis becomes very serious.

In all cases of gangrene or ulceration of these mucous surfaces the greatest care should be exercised to prevent the closure or narrowing of the passages by union. The parts should always be separated, and the surfaces not allowed to come in contact with one another.

NOMA PUDENDI.—This condition has been by some considered to be identical with gangrene, and by others to be a direct forerunner of it. Its frequent occurrence in institutions where there are many inmates points towards its infectious character, and investigations recently made suggest, if they do not actually prove, the presence of micro-organisms, though the specific cocci have not been isolated. The primary cause in children is usually some pre-existing lesion induced by irritation or inflammation. A resulting gangrene should be carefully guarded against. Antiseptics and local soothing applications are indicated, and constitutional treatment for building up the whole system. Iodoform has been recommended as a specific. (Mann.)

LUPUS is comparatively rare in the very young, and but few cases have been recorded. As to the exact cause there seems to be a difference of opinion. Dr. Taylor[1] thinks that too much prominence has been given to syphilis as a causative factor of this lesion, although it certainly has much to do with it. In children, unless it be a congenital defect, the growth may be caused by inflammation, irritation, traumatism, or some constitutional affection, as tuberculosis. The size varies, in some cases the labia becoming greatly hypertrophied and very vascular. Whether it is identical with lupus of the face is still a question, though the majority of writers still agree with Huguier, who first advanced the theory. Dr. Grace Peckham[2] has suggested that the term lupus or esthiomène be set aside and that of hypertrophic ulcer of the vulva substituted, prefixing as an adjective the cause of the lesion, if that be discoverable.

The treatment should be, where possible, radical. Cauterization of the ulcers and of the bleeding surfaces is recommended by Dr. Peckham. Antisyphilitic measures are always indicated where a suspicion of a venereal or constitutional cause exists.

TRACHOMA PUDENDORUM is a condition which Prof. Tarnovsky, of St. Petersburg,[3] has found. On the labia are yellowish or grayish nodules about the size of a pin-head, "surrounded by a hyperæmic halo." The feel of the affected part is gritty, like sand, and crepitation is obtained by scratching with any hard substance. The growth contains innumerable micrococci, which are believed to be the cause. Sometimes there is pruritus, which is relieved by cold. Prof. Tarnovsky advises superficial scarification; applications of silver nitrate, five to ten grains to the ounce of water; carbolic acid, five per cent.; or corrosive sublimate solution, in the proportion of one to two-thousand. The condition is infectious.

[3] Jour. Akusherstva.

FOREIGN BODIES have sometimes been found to give rise to irritations of the vulva, resulting, unless discovered promptly, in serious lesions. Bökai[1] relates a case of strangulation of the clitoris in a young girl, produced by her having tied a piece of string around its base. In this instance a knife was resorted to. Local treatment, to relieve irritation, and the removal of the cause, are, as a rule, all that will be required, provided the lesion has not been of too long duration.

DISEASES OF THE OVARIES AND TUBES.

By HOWARD A. KELLY, M.D.

WHILE within the past decade familiarity with diseases of the uterine appendages—the Fallopian tubes and the ovaries—has become somewhat widely diffused, so that the general practitioner, meeting a case of long-standing severe pelvic pain, or persistent profuse menstrual flow, or other severe distress of pelvic origin, may now at least suspect the existence of something more than mere functional disorder and seek special advice, the existence of such diseases in children is not only not as yet systematically treated, but is not even ranged within the limits of the extraordinarily rare in the various text-books on pelvic pathology.

One of the most admirable scientific treatises upon the diseases of the female sexual organs in children, by Prof. Hennig, of Leipsic,[1] seems as yet to have attracted but little attention in the English-speaking world, and this important branch of diagnosis, pathology, and therapy still rests in the mists of the unknown. Nevertheless, the writer is convinced, from personal observation, from numerous scattered notices in the journals, and from communications from specialists, that both for the gynæcologist and for the specialist in children's diseases there lies in this direction a rich uncultivated field, which will in the future yield abundant reward to the patient collector and analyst.

The importance of a careful consideration of all the diagnostic signs associated with the pelvic diseases of girls is both absolute and relative. The subject derives its *absolute* importance from the fact that a number of localized diseases strictly limited to the pelvis, such as ovarian and dermoid cysts, and inflammation of the tubes and ovaries, have been recognized and successfully treated within the period of childhood; it derives its *relative* importance from the bearing of the proper healthy development of these organs, which is continued through childhood, upon the whole life-history of the adult. Here within the limits of childhood often creep in those localized disturbances, or diseases arising from a dyscrasia, which render the regular cyclical functional activity of these organs after puberty, whether it be in the act of menstruation or in that of childbearing, a matter of serious difficulty or even of impossibility.

---

[1] Gerhardt's Handbuch der Kinderkrankheiten, 4ter Band, 3tte Abtheilung, Tübingen, 1878.

GENERAL CLASSIFICATION.

Congenital malformations, such as ovaries and tubes displaced into the canal of Nuck, or absent or rudimentary ovary or tube, scarcely come within the category of diseases, owing their existence to conditions which it is at present beyond our power to trace.

Imperfect development of the ovaries and tubes, by which, with the uterus and the rest of the genitals, and the body at large, these organs progressively change from the infantile type to that characteristic of puberty, is either associated with the same mysterious causes producing congenital defects, or else is connected with a retardation in the general bodily development, due to rickets, syphilis, or malnutrition, in which latter case they are more properly considered under the topics hygiene of childhood or dyscrasiæ.

Tumors and Inflammations of the Ovaries and Tubes.—Although in a quiescent developmental state, the ovaries and tubes in childhood are in a lesser degree liable to the same diseases as in adult life. Thus, numerous cases of ovarian tumors have been recorded, dermoid tumors, sarcomata, and inflammation of the tubes during exanthemata. They are also liable to tuberculosis and to syphilitic inflammation.

Diseases due to Sexual Activity.—If we were to take into consideration all the injuries arising in cases of rape, as well as in the early marriages in India and other tropical countries, with especial reference to phenomenal cases of childbearing in childhood, we might easily reproduce the whole domain of gynæcology as pertinent to our present inquiry. However, we will not trench upon this ground further than to substantiate the fact that gonorrhœa and pus-diseases of the ovaries and tubes may be found in children.

DIAGNOSIS IN GENERAL.

The avenues of approach for examination, and the means of making a diagnosis of diseases of the pelvic organs in children, present very important differences from the means of approaching the same structures in the adult woman. The history, in cases associated with much pain, rests more upon very general indications as to the region of the body affected, to be determined in the case of very young children more by the habit of the body of the sufferer, in the absence of the possibility of succinct statement, and by such facts as the very unsatisfactory observation of attendant adults may have developed.

The physical examination has two avenues,—the rectum and the abdomen.

The vagina, the chief avenue of approach for the palpation of periuterine structure in the adult, cannot be used at all in small children; and in those who are older, and in whom a small index finger could possibly be introduced, the tightness with which the finger is grasped and the shortness of the canal very seriously limit its excursus in the attempt to palpate, demonstrating the futility of seeking information *per viam vaginæ*.

Rectal Palpation.—The rectum, however, offers an approach as satisfactory as the vagina is unsatisfactory, for by means of a carefully-applied rectal touch much more can be discovered than by both rectum and vagina in the adult. The lower bowel should be well emptied beforehand by a soap-and-water injection, and the index finger, with a short nail and well oiled, gently introduced, avoiding with the utmost care any roughness or haste in the procedure, thus obviating any lacerations of the delicate integument at the anal orifice, or the more serious injury, not only possible, but probable under a rough examination, of rupture of the coats of the bowel.

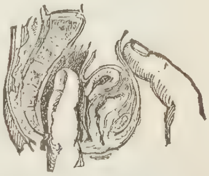
The difficulty sometimes experienced in the adult in finding the lumen of the bowel above the large lax ampullar distention (the rectal pouch) does not exist here, and the smaller and straighter canal is readily followed by the index finger gently pushing its way upward into the pelvis.

While in the adult the finger can with difficulty reach the deeper portions of the pelvis, and often reaches the ovaries and tubes only by firm upward pressure, with considerable invagination of the skin-surface, in the smaller pelvis of the child the finger at once easily touches all parts.

Upon pressing forward with the pulp of the examining finger, the first object distinctly recognized is the relatively bulky cervix; above this can be traced, like a broad cord, the uterine body. The ovaries and tubes, if enlarged in any way or involved in inflammatory masses, can be distinctly recognized, but in the normal condition cannot be separated from numerous similar structures felt gliding over the pulp of the finger.

Combined Rectal and Abdominal Palpation.—While the rectal touch is the most certain way of approaching tubes and ovaries to be questioned as to their condition of health or disease, the same examination combined with palpation by the other hand *per abdomen* is greatly enhanced in its value. (Fig. 1.) Thus, while soft, yielding, and small structures escape the detection of one hand by gliding at once to one side or the other as soon as pressure is made upon them, when counter-pressure is made by means of the outside hand pushing down thoroughly the superior strait from above, all the structures in question are readily caught and detained, and their relations and consistence determined without difficulty. In this way the uterus is most clearly felt, the ureters, on account of their peculiar course, are readily palpated, the ovaries are often recognized, and the tubes, in common with the other broad-ligament structures, slip with a characteristic jumping sensation between the fingers.

FIG. 1.



Rectal and bimanual palpation in the child.

Anæsthesia in the Pelvic Examination of Children.—In wellconditioned children, where the belly-walls are often very fat and distended, or where resistance is probable or much pain is liable to be produced in the course of an examination which it is important should be thorough, it is best to anæsthetize at once. Indeed, anæsthesia is advisable in almost all cases, so rapid is it in taking effect, so short is the duration, and so slight are the after-effects. The entire relaxation, and the absence of all resistance, thus produced afford every facility for the most complete examination.

Exploratory Incision.—In all cases of doubtful diagnosis where the health or life of the child seems seriously threatened by an abdominal growth, the exploratory incision offers a safe and satisfactory solution of the difficulty. If the growth is of such a nature that it can be removed, the operator should be ready to complete the operation at once; if, however, owing to its attachments, it is impossible to remove it, the incision can be closed within five or ten minutes, and the patient left in no worse condition than she was in immediately before this simple operation. The incision should be carefully made in the median line, beginning about an inch above the symphysis pubis, and extending an inch and a half upward. After incising the skin, the subcutaneous fat, the white tendinous structures composing the linea alba, and the subperitoneal fat, the peritoneum appears as a delicate membrane, which should be picked up between two forceps, raising it in a distinct fold; a slight nick with the knife opens the sac, and at once the air enters the small opening and the intestines drop away out of the reach of danger. Removing the forceps and introducing both index fingers into this opening, it should then be torn to the full extent of the external incision, after which one finger can be carried into the pelvis to conduct the exploration.

It is best to explore in an orderly manner, according to rule, seeking out the uterus first, as a landmark most easily recognized, then palpating to the right and to the left from this as a fixed point, over the broad ligaments, tubes, and ovaries.

It frequently happens that a considerable accumulation of ascitic fluid is found at the same time. A great deal of relief will often be experienced if nothing more is accomplished than its complete evacuation.

In thin walls six and in thick walls four silk sutures will close the incision. A powder of iodoform and boracic acid (℞ Iodoformi, ʒss; Pulv. acidi borici, ʒiv. M.) having been dusted freely on the line of incision, absorbent cotton placed over this, and an abdominal bandage applied, the patient is ready to be lifted from the table and returned to bed.

The dressing need not be disturbed for a week, when all the sutures are removed at once, and the sides of the incision supported for a week longer by narrow adhesive strips.

It rests with the general practitioner to conduct these cases to a specialist and to afford them the benefit of this procedure. There is no possible reason why the rule so universally recognized in the treatment of doubtful conditions in the adult should not equally apply to the child. Simple as the exploratory incision is, its safety lies in the most rigid application of the antiseptic principle throughout. Carelessly undertaken, in forgetfulness of this principle, it will surely entail a certain percentage of deaths.

OVARIAN TUMORS.

In Sir Spencer Wells's list of one thousand ovariotomies, three operations upon children are recorded, giving an average which probably exhibits with some degree of accuracy the relative frequency of this affection in juvenile and in adult life, some allowance being made for the fact that children are not so readily brought to operation as adults.

The largest tumor ever removed from a child was operated upon by Dr. H. Marion Sims (personal communication) in 1883. The patient, aged eleven and a half years, came to Dr. Sims from Tarrytown, New York, where she had not escaped the comment of the village gossips, who declared her to be in a family way. Her abdomen was enormously distended, and she had been unable to lie down for several months. Dr. Sims diagnosed a multilocular ovarian cyst, and operated, removing a cyst made of loculi containing solid and fluid material. The whole tumor weighed sixty-one pounds, the patient weighing seventy-six pounds. The recovery was excellent, and the patient is still living and well.

Such an operation, trying the mettle of the operator and the endurance of his frail patient, teaches us in no undecided manner what skilful aid may do even in the most extreme cases.

The smallest tumor of which I find a record of operation in childhood is a case recorded by T. Spencer Wells.[1] The tumor weighed but two pounds. The little girl, eight years of age, was a patient of Dr. Lane, of San Francisco: she made a good recovery, and was living and well seven years later.

Dr. Boldt, of New York, has operated upon a patient four years old.

Dr. Joseph Taber Johnson, of Washington, has had two cases of ovarian tumors in children. The first patient, twelve years old, was referred to Dr. Thomas, of New York, who removed a sixteen-pound ovarian cyst; within a year a tumor equally large developed in the other ovary, and before she could be operated upon this burst, and she died suddenly.

Dr. Johnson has himself operated upon a girl of thirteen, removing successfully a tumor weighing eight pounds; she was fifteen at date of writing, and had not yet menstruated.

Prof. Koeberlé, whose genius has anticipated most of the steps of modern advanced gynæcology, reports a case[2] in the *Gazette Médicale de Strassbourg*, 1876, in which he successfully operated upon a girl aged thirteen, removing a large multilocular ovarian cyst through an incision sixteen centimetres in length.

---

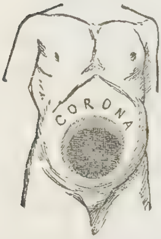
[1] Ovarian and Uterine Tumors, London, 1882, p. 374, Case 604.

[2] Hennig, loc. cit., p. 48.

Diagnosis of Ovarian Tumors.—The diagnosis of an ovarian tumor will be made by the discovery of a large multilocular encysted mass of slow growth springing from a pelvic attachment, yielding everywhere over its mass a flat percussion-note.

The ovarian tumor, having a pedicle at the broad ligament of greater or less length, and being free to move, as soon as it escapes from the pelvis is floated up and pushed to the front by the lighter intestines; in this way a dull area corresponding to the prominence of the tumor is produced, while above the tumor, and pressed down into the flanks, lie the intestines, giving a crescentic area of tympany, appropriately called the *corona ovariana.* (Fig. 2.)

FIG. 2.



Area of tympany around an ovarian tumor, called the "corona ovariana."

DIFFERENTIAL DIAGNOSIS.—The importance of being able to make a correct diagnosis before operation has greatly diminished since the safety of the exploratory incision has been established, but for scientific accuracy every simple means at our command will naturally be first employed.

The *exploratory puncture,* so much employed a few years ago, in the days when "humoral" pathology held sway in the study of abdominal tumors, will now, in view of its uncertainty as a means of diagnosis, and its dangers, and of the equal if not greater safety, with the added certainty, of the exploratory incision, be scarcely admitted under any circumstances. The diagnosis will be determined upon the facts afforded by the history, inspection, percussion, and palpation. The differential diagnosis of any single disease in the realm of medical science derives its importance not from the lengthy list of all the various pathological conditions which can be enumerated as bearing any of its important characteristics and hence liable to be mistaken for it, but from a certain class or classes of conditions which are constantly cropping up and in one way or another demanding separation from the disease in question. The disease thus acquires, apart from the characteristics which it has when viewed alone, a certain definite physiognomy derived from its more or less constant relation or association with other diseases. Some of these characteristics are equally appreciated by all operators, while to a certain extent the difficulties and experiences of each particular operator give a certain amount of individualization to the disease in question. Thus, "cystic ovarian tumor" in the adult at once calls up a well-defined picture of fibroid and fibro-cystic tumor, of dermoid and parovarian cysts, with a background of renal, splenic, intestinal, mesenteric, and malignant ovarian tumors. In children, on the other hand, the picture of the conditions which are liable to cause an error in the diagnosis thus summoned is very different. They are dermoid cysts and sarcomata of the ovaries, and malignant and cystic renal diseases, together with various atypical retro-peritoneal renal affections. The prognosis in children, therefore, in advance of accurate investigation, is far more serious than in adults.

It is not the purpose of the writer to enter elaborately into the intricacies of differential diagnosis. Suffice it to say that *dermoid cysts* are frequently found double, and are of much slower growth than ordinary ovarian cysts, and consequently (as Hennig observes) are much more liable to be carried over into the years of puberty than the ovarian cysts.

Malignant diseases in general are to be distinguished by their more rapid growth and by the marked affection of the general health of the patient, as well as by the frequent association of large ascitic accumulations.

If this accumulation be tapped under the impression that it is an ascites proceeding from hepatic or renal disease, the fluid will often be of a deep-red color, from the abundant red blood-cells present, or will contain in the thick sediment vacuolated or round and spindle cells. At other times the examination of the fluid is perfectly negative.

In retro-peritoneal disease of a malignant nature, when the tumor springs from the pelvis its base is broad, and hence it is more or less immobile, and the function of one pelvic organ or another is often seriously interfered with. Thus, in the case of a child three years old in the hands of the writer, a soft sarcoma eight centimetres in diameter, springing from the anterior face of the sacrum, in position, shape, and consistency closely simulated an ovarian cyst, but its retro-peritoneal origin was to be inferred from the marked deviation of the rectum and from the frequent agonizing efforts at micturition caused by a large hydro-ureter of the right side.

Malignant or congenital cystic disease of the kidneys requires careful consideration and separation from ovarian tumors. In a certain percentage of cases[1] of malignant disease hæmaturia will give the clue to the difficulty; in the majority of cases the urine is in no respects abnormal.

Before the tumor has reached a size sufficient to fill more than one-fourth of the abdomen, its renal origin may be detected by the reniform shape, by its position more in one or other (chiefly the right) flank, by the greater facility with which it can be displaced into either lumbar region, and, above all, by the clear percussion-note over the tumor. When larger in size, the more elongate barrel-shaped abdomen contrasts markedly with the prominent spheroid of the ovarian cyst. In some cases the exploratory incision alone will solve the difficulty.

An enlarged spleen is to be recognized by its notched border, its regularity of outline, and its peculiar resistance, together with the mobility and the readiness with which the tumor can be displaced into the left hypochondrium and its evident want of pelvic attachment.

Technique of Ovariotomy in Children.—The conduct of the operation for the removal of an ovarian tumor in a child is, in general, similar to the same operation in the adult, and may be briefly summed up in the stages enumerated below.

Daily baths should be given beforehand, to cleanse and soften the skin.

---

[1] Three times in twelve cases, according to Dr. Victor Faludi.

Twenty-four hours before the operation, the bowels should be well opened; and half an hour before, a small dose of morphine with thirty grains of subnitrate of bismuth should be administered, to insure contraction of the intestines.

1. Perfect antisepsis (whether attained by a thorough preliminary use of soap-and-water or by chemicals).

2. An incision in the linea alba large enough to allow rapid work.

3. Exposure of the cyst, and puncture and evacuation of its contents.

4. Turning the cyst inside out, like an inverted sac, through the incision.

5. Ligation of the pedicle in two or more parts.

6. Cleansing of the peritoneum, including the removal of all water, escaped cystic contents, and blood, usually gravitating into Douglas's pouch and the iliac fossæ.

7. Drainage by means of a straight glass tube, if there is any persistent oozing, or complete closure of the incision by means of silk sutures, about four to the inch.

Adhesions to abdominal walls, pelvic viscera, omentum, and intestines must be separated with extreme care, so as to leave no bleeding points, and to avoid sacrificing any of the coats of the viscera. This can be accomplished where the tumor is attached to the omentum, or where the adhesions are in the form of bands, by double tying and cutting between. Flat adhesions can be separated by carefully peeling apart the annexed surfaces with thumbs and forefingers, always remembering that, if the adhesion is inclined to tear, the coats of the tumor which is being extirpated must be sacrificed.

In one important respect this operation when performed in the child differs from the same operation in the adult,—that is, in the far greater liability to serious shock. It is necessary to bear in mind continually that the size of the tumor in proportion to that of the subject is far greater in children, that the relative exposure to evaporation and loss of heat is much greater, and that the same loss of blood which in the one case would at the most produce a shock to be recovered from in two or three days would in the other prove inevitably fatal.

The same rule applies also to the time consumed in the operation. The diminished powers of resistance of the more delicate child's organism must be constantly borne in mind.

DERMOID CYSTS.

Dermoid cysts are frequently met with in childhood. In the closed abdomen they present all the characteristics of simple ovarian cysts. They contain abundant fat, either liquid or of a tallowy consistence, skin, hair, sebaceous and sweat glands, bones, and teeth. They are much slower in growth than ovarian tumors, and hence are liable to be carried much longer, even into the years of puberty.

CANCER.

Cancer of the ovary has been observed in childhood. Hennig (*loc. cit.*) was able to collect four cases in 1878, in addition to which he has since added the references cited at the end of this article.

The writer operated upon a remarkable case of this kind several years ago. The patient, twelve years old, was an unusually bright child, of very slight frame. The abdomen began to swell very suddenly. She was tapped a number of times, discharging dark bloody fluid containing round cells. The fluid reaccumulated very rapidly, and she was evidently fast becoming exhausted by the drain. At the operation the writer removed a large sarcoma of the ovary, flat, and large enough to fill a hat, attached by a broad membranous pedicle, about an inch and a half in length, to the left broad ligament. The patient made a perfect recovery, but succumbed two years later to an attack of dysentery.

TUBERCULOSIS.

Tuberculosis of the ovaries or tubes will with difficulty be recognized during life, or will at the utmost be detected upon making an exploratory incision.

Hennig cites a case of a child from Amboyna, twelve years old, who had tubercular disease of both ovaries, one tube, and the uterus. Gusserow (see literature by Hennig) reports cases of tuberculosis of the ovaries and uterus without participation of the tubes, and Kiwisch and Neureutter cite cases of tuberculosis of the tubes and uterus.

PUS DISEASES.

Inflammatory diseases involving the tubes and extending to the ovaries, sealing the tubes, or extending to the pelvic peritoneum, undoubtedly occur, although rarely reported.

Dr. M. Sänger, of Leipsic, related to the writer a case in which a man with gonorrhœa infected his whole family, including a little daughter, who developed all the symptoms of an acute pelvic peritonitis, in common with a well-marked gonorrhœa, from which she recovered only after a protracted illness.

Dr. Edis[1] reported a case of a child twelve years of age, dying after a wasting illness of four months, in which he found a pelvis full of pus surrounding a ruptured ovary and a cheesy tube.

EXANTHEMATOUS INFLAMMATION.

As early as 1851 Hennig observed hyperæmia and infiltration of ovaries and tubes in scarlet fever.

The effects of the severer forms of the exanthemata upon the female genitals urgently demand more careful observation and the report of a number of cases, to assist in determining the relation of these diseases to dysmenorrhœa, sterility, and imperfect development in later life.

ABNORMALITIES OF THE FEMALE GENITAL ORGANS AND MAMMARY GLANDS.

BY CLARA MARSHALL, M.D.

ABNORMALITIES of the female sexual organs when studied in connection with the development of the human embryo no longer assume the character of natural curiosities, but become explainable, in the large majority of instances, under the head of *arrest of development*. To the scientific student they are of perhaps greater interest than are the normal types, because in them is afforded an opportunity to study in a permanent form certain transitory embryonic states. These malformations have been aptly spoken of as "development caught in the act and fixed permanently for after-investigation."

The space allotted to this paper will permit only a cursory glance into this illimitable and fascinating field of investigation.

Since most of the malformations of the genitalia do not receive attention and are not even suspected until some defect in function demands relief, it happens that most of the recorded cases are those which were seen first in adult life. This being the case, it necessarily follows that most of the illustrations made use of by the writer have been taken from reports of cases which were noted at or after the period of puberty.

Some account has already been given of the normal anatomy of the female sexual organs at birth, and allusion has been made to their mode of development (vol. i. pp. 41, 42). It may be well, however, to refer to the fact that the Fallopian tubes, the uterus, and the vagina are developed from the ducts of Müller, which appear first as solid filaments, and then as tubes whose walls approach each other and afterwards (at the lowest part) coalesce, with a final absorption of the septum so that the two tubes unite in one, forming the uterus and vagina. Above they remain separated as the right and the left Fallopian tube. The illustration on the following page (Figs. 1, 2, 3, 4), from Skene, is suggestive of these changes.

OVARIES.

The rarest of all the abnormalities of the sexual system is the *absence* of both ovaries, and it is also the abnormality which is most frequently associated with defective development of the remaining sexual organs. According to Courty, "in two-thirds of the cases in which absence of the ovaries has been observed, the vagina, uterus, and Fallopian tubes were also absent; in the remaining third the uterus existed, but was imperfectly developed, presenting after puberty the characteristics of fœtal or infantile life." A diagnosis of this condition during infancy and childhood is not likely to be made except upon the post-mortem table; it may be suspected at puberty if there is no evidence of ovulation, and especially if there is evidence of the non-existence of the uterus and vagina.

FIG. 1.

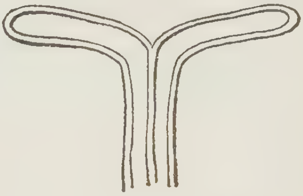
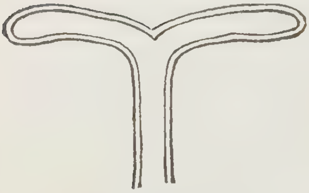
FIG. 2.



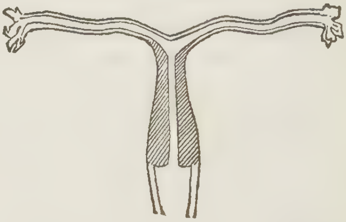
Coalescence of ducts.

FIG. 3.



Disappearance of septum.

FIG. 4.



Appearance of fundus and cervix.

Rudimentary ovaries in the living subject are diagnosticated or suspected for the same reasons as those just given. While rudimentary ovaries may exist with a fully-developed uterus and external genitalia, they are far more frequently found in connection with a rudimentary uterus. It is also important to remember that occasionally fully-developed ovaries may be found associated with non-development of the uterus.

The ovaries may be more or less deeply notched, or the fissure may be so extensive as to divide the ovary into two segments, not a very rare abnormality; or there may be an *accessory* ovary: in a most interesting case of the latter condition reported by Winckel there were three ovaries and three ovarian ligaments.[1]

The presence of a third ovary becomes of especial significance during the child-bearing period, as a probable explanation of those rare cases of pregnancy following a double ovariotomy.

A *single* ovary is not unfrequently associated with a one-horned uterus and upon the same side with the undeveloped horn.

The ovaries are developed in the abdomen, gradually descending during intra-uterine life, reaching the brim of the true pelvis at birth, and after birth gradually assuming their final position at the sides of the pelvis. There may be *excessive descent*, in which case the ovary may be found in the inguinal canal or even in the labium majus, and it may drag with it the Fallopian tube and the uterus.

---

[1] Pathologie der weiblichen Sexualorgane, p. 28, table xxxiv., Fig. 7.

FALLOPIAN TUBES.

Among the abnormalities of the Fallopian tubes their complete *absence* (usually associated with absence of the uterus) is first in the order of rarity.

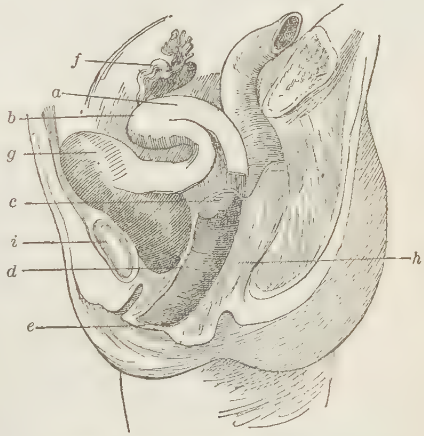
Remembering the origin of the Fallopian tubes from Müller's ducts, it is very easy to understand that there may be any degree of departure from the normal type, corresponding to the stage of development at which the arrest has taken place. Absence of one tube is usually associated with a uterus unicornis.

The tubes may be *rudimentary*, or they may be supplied with *supernumerary fimbriæ* together with *supernumerary ostia;* or they may fail to descend from the lumbar region, or there may be *excess* of *descent* (hernia): the Fallopian tubes may descend alone (this is very rare) into the inguinal canal, or, as is more frequent, they may accompany descent of the ovaries.

UTERUS.

The uterus in the child is higher above the pelvic brim than in the adult, and, if so movable an organ can be said to have a normal position, its most frequent position is that of slight forward inclination, with flexion of the body upon the cervix. The position of the uterus, together with its relations at birth to other organs and to the pelvic cavity, is illustrated by Fig. 5, from Courty.

FIG. 5.

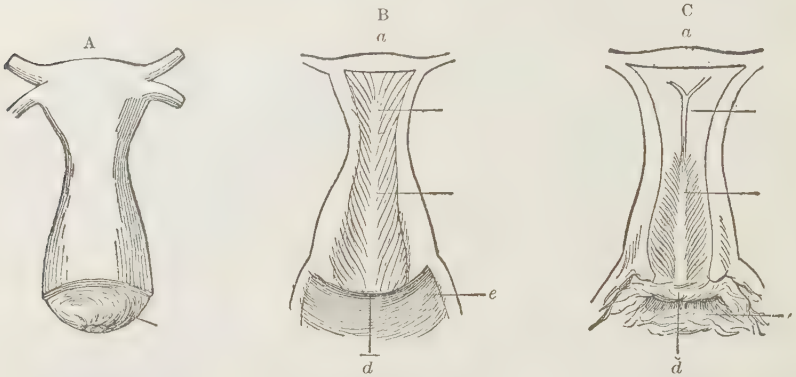


UTERUS OF A FŒTUS AT BIRTH, side view, seen in its relations, showing the normal anteflexion natural during fœtal and infantile life. (From Courty, after Boullard and Bourgery.)—*a*, body of uterus flexed forward; *b*, fundus uteri looking forward; *c*, cervix; *d*, vagina; *e*, hymen; *f*, Fallopian tube, behind which the ovary is seen; *g*, bladder; *h*, rectum; *i*, symphysis pubis.

Fig. 6, also from Courty, illustrates the following characteristics of the uterus at birth: its size, the distribution of the arbor vitæ, which extends to the fundus, the absence of an internal os, the two cavities of the body and the neck being continuous with each other, the larger size of the neck and its relatively thicker walls as compared with the body, the shortness of the vaginal portion of the cervix and its cylindrical shape. The body is more flattened than in the adult, and its upper border is straight or even slightly concave.

If the growth of the organ stops at this point, the characteristics which have just been described as normal in the child constitute in the adult an abnormality correctly styled the "infantile uterus."

Fig. 6.

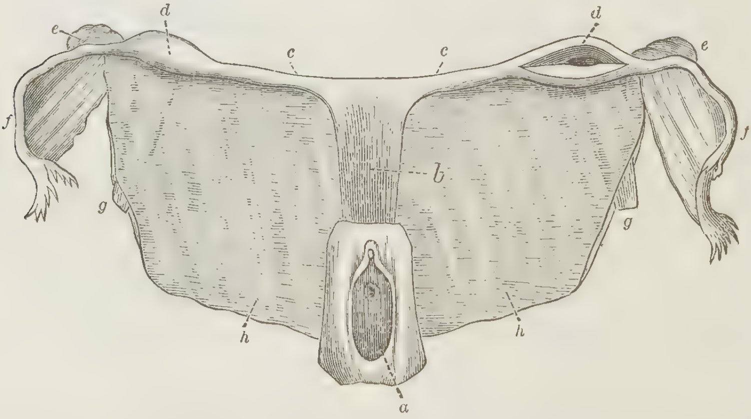


A. Uterus at Birth, natural size. B. Cavities.—*b*, cavity of the body, showing the arbor vitæ: the fundus, *a*, and the walls are relatively thin; *c*, neck, the walls of which are very thick; *d*, vaginal portion of the cervix; *e*, vagina. C. Section of Uterus at Seventh Year, open, of natural size.—*a*, fundus; *b*, body, the cavity of which still shows a trace of the internal longitudinal fold resulting from the union of the two primitive uteri and forming a continuation of the arbor vitæ of the neck; *c*, neck, still longer than the body and with thicker walls; *d*, vaginal portion of the neck; *e*, vagina.

The uterus may be *absent,* in which case there is usually absence of or defect in other portions of the genital system or elsewhere in the body.

Rudimentary Uterus.—The uterus may consist of a band of connective tissue interspersed with muscular fibres; it may be a solid nodule of fibrous tissue; it may be that rudimentary form described by Mayer, in which the position usually occupied by the normal uterus is filled by a body composed of muscular fibres and connective tissue, and sending off from each side of

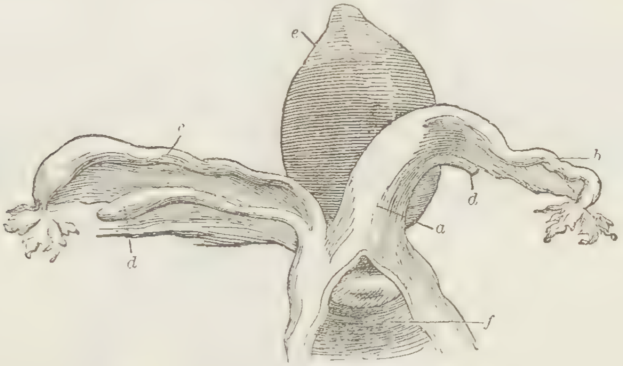
Fig. 7.



Uterus Bipartitus.—*a*, vagina; *b*, a band of cellular tissue mixed with muscular fibres, having the form of a uterus; *c*, *c*, muscular cords representing the uterine cornua and terminating in enlargements, *d*, *d*, of the size of a bean, hollowed out into a cavity capable of holding a lentil and lined with mucous membrane; *e*, *e*, rudimentary ovaries; *f*, *f*, oviducts; *g*, *g*, round ligaments; *h*, *h*, broad ligaments. (Küssmaul, after Mayer.)

its superior border a cord, ending in a swelling, which may or may not be solid, and which is found at the insertion of the round ligament. Fig. 7 represents such a uterus, which was named by Mayer *uterus bipartitus.*

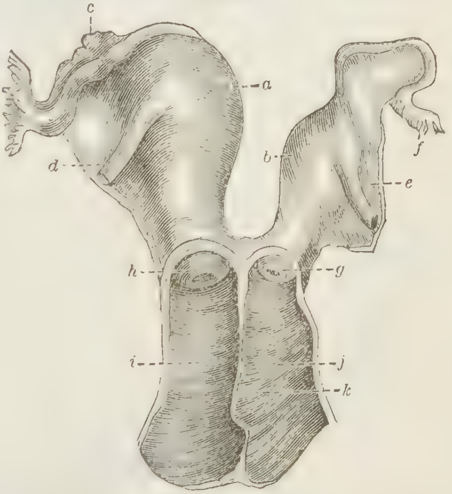
Fig. 8.



Uterus Unicornis of a Child, seen from behind. (After Pole.)—*a*, right unicorn uterus; *b*, right Fallopian tube; *c*, left Fallopian tube; *d*, *d*, ovaries; *e*, bladder; *f*, vagina, in which is seen the uterine orifice.

This form of non-development is not necessarily associated with non-development of the ovaries. The breasts and external organs of generation may also be well developed.

Fig. 9.



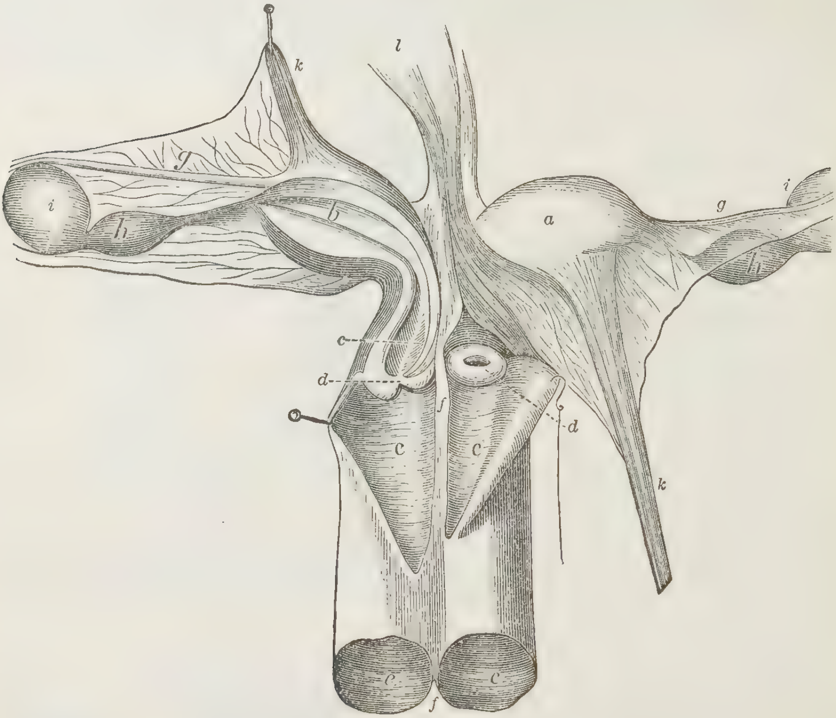
Uterus Didelphys.—*a*, right cavity; *b*, left cavity; *c*, right ovary; *d*, right round ligament; *e*, left round ligament; *f*, left tube; *g*, left vaginal portion; *h*, right vaginal portion; *i*, right vagina; *j*, left vagina; *k*, partition between the two vaginæ. (De Sinéty, after Ollivier.)

Uterus Unicornis.—In this variety of arrest of development one Müllerian duct has been developed while the other is either entirely absent or exists in a rudimentary state. The fundus (if we may be allowed so to call the fully-developed single horn) is curved to one side, and is continuous with the Fallopian tube and ovary. There may or may not be a Fallopian tube and ovary connected with the undeveloped horn of the uterus. There may be an absence or a rudimentary condition of the kidney on the same side with the undeveloped horn. (Fig. 8.)

Uterus Didelphys.—This deformity originates in an entire want of contact of those portions of the Müllerian ducts which should by their coalescence form the uterus. Consequently there are two separate uteri, or rather the two halves of the uterus are separate. (Fig. 9.)

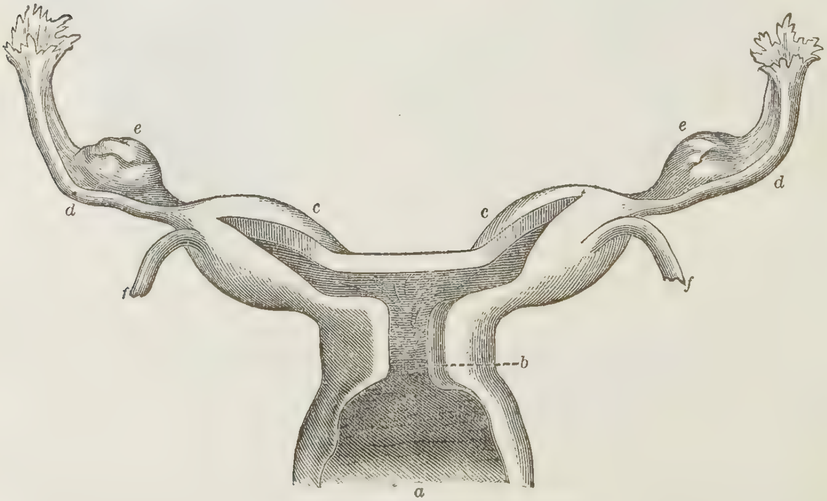
This variety is also known as *uterus duplex separatus.*

FIG. 10.



UTERUS BICORNIS DUPLEX.—*a*, left horn; *b*, cavity of right horn; *c*, right cervical canal; *d*, *d*, external orifices; *e*, *e*, the two vaginal canals; *f*, the partition between the vaginal canals; *g*, *g*, tubes; *h*, *h*, ovaries; *i*, *i*, cysts of the ovaries; *k*, *k*, round ligaments; *l*, suspensory ligament of uterus. (Küssmaul, after Cassan.)

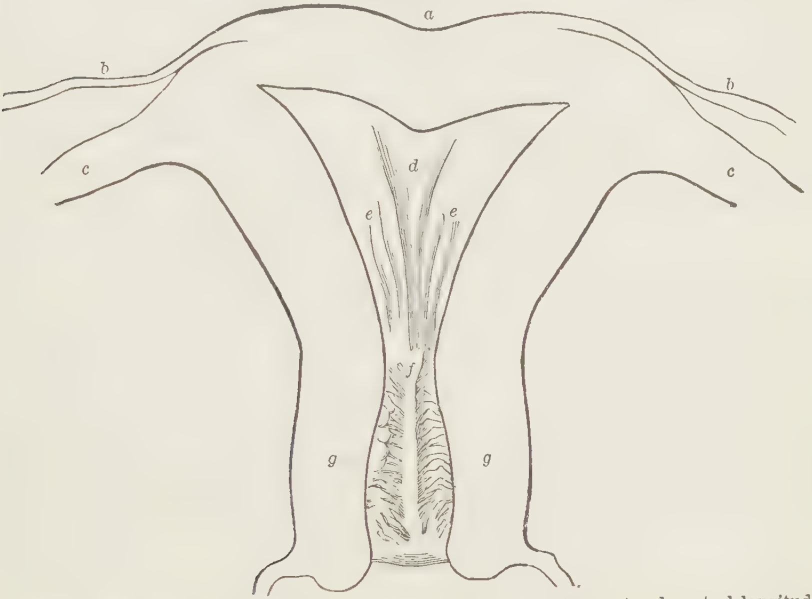
FIG. 11.



UTERUS BICORNIS UNICOLLIS.—*a*, vagina; *b*, single neck; *c*, *c*, horns; *d*, *d*, tubes; *e*, *e*, ovaries; *f*, *f*, round ligaments. (From Küssmaul.)

Uterus Bicornis.—If those portions of the ducts of Müller which coalesce to form the upper part of the uterus fail to unite, the result is a two-horned uterus. If the cavities remain separate throughout, it is known as a *uterus bicornis duplex.* (Fig. 10.)

FIG. 12.

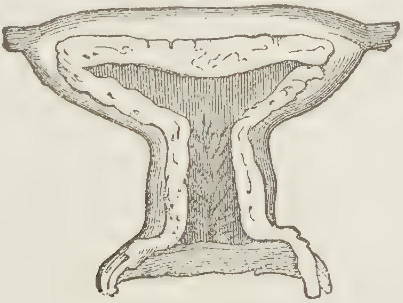


UTERUS ARCUATUS.—*a*, indented fundus; *b*, *b*, tubes; *c*, *c*, round ligaments; *d*, central longitudinal ridge on the posterior wall of the cavity of the body; *e*, *e*, lateral ridges of the same; *f*, internal os; *g*, *g*, cervix uteri. (From Küssmaul.)

There may be a two-horned uterus with a single cervix,—*uterus bicornis unicollis* (Fig. 11).

A very slight tendency to separation may exist, shown by a depression in the fundus, and, from its resemblance to a heart, such a uterus is known as *uterus cordiformis* (*uterus arcuatus*) (Fig. 12).

FIG. 13.

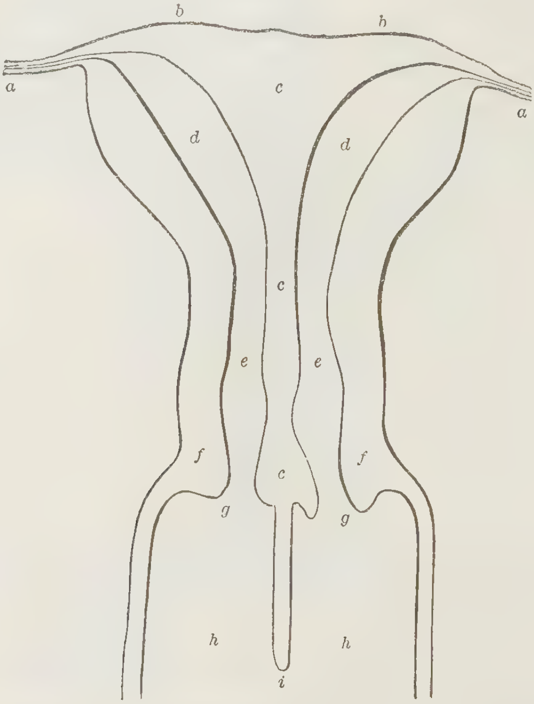


UTERUS INCUDIFORMIS.

Or there may be the anvil-shaped uterus, in which the upper border does not present the normal degree of convexity (*uterus incudiformis*) (Fig. 13).

Uterus septus is one which to outward appearance is normal, but in which the cavity is divided by a longitudinal septum into two halves. A complete division constitutes a *uterus septus duplex* (Fig. 14).

FIG. 14.



UTERUS SEPTUS DUPLEX.—*a, a*, tubes; *b, b*, fundus of double uterus; *c, c, c*, partition of uterus; *d, d*, cavities of uterine bodies; *e, e*, internal orifices; *f, f*, external walls of the two necks; *g, g*, external orifices; *h, h*, vaginal canals; *i*, partition dividing the upper part of the vagina into two halves. (From Küssmaul.)

If the septum is incomplete, the deformity is known as *u. subseptus;* and again the u. subseptus has various subdivisions according to the extent of the septum. If the partition extends from above downward to the external os (leaving one os), it is a *u. subseptus uniforis:* a still shorter partition, just reaching the internal os, is a *u. subseptus unicollis.* The vagina and neck may be divided without division of the body of the uterus.

Uterus parvicollis is one in which the neck is undeveloped. *Uterus acollis* is one in which the neck is absent.

Hernia of the Uterus.—Congenital inguinal hernia may be complicated with hernia of the uterus, or much more frequently with hernia of the uterus and its appendages, in which latter case the appendages descend first and the uterus is dragged down afterwards. Courty states that in the "Atlas of Bovin and Dujes, Pl. XI. Fig. 3, there is a drawing after Cloquet of a right *crural* hernia of the uterus, ovaries, and Fallopian tubes in a newly-born child, in which the fundus of the uterus seems to have been first displaced."

VAGINA.

The vagina may be *absent*, being represented only by a cord, in which case the uterus may be absent, rudimentary, or well developed. It may be narrow (*stenosis*), frequently associated with a bicorn uterus. It may be *double*, a continuation or not of a so-called double uterus. It may be entirely closed (*atresia vaginæ*) by one or more transverse septa or by an imperforate hymen (*atresia hymenalis*). In the "London Obstetrical Transactions" for 1887 (vol. xix.) a case is reported in which atresia of the vagina was found in a newly-born child combined with a large cyst formed by the distended upper part of the canal and occupying most of the abdomen: the uterus communicated with the cyst.

HYMEN.

The hymen, according to recent observations, especially those of Tardieu, may vary greatly in appearance, even within normal limits. The most marked abnormalities are imperforate hymen (absolutely no opening), biperforate hymen (two openings), which may or may not be continuous with a double vagina, and cribriform hymen (perforated like the rose of a watering-pot). The hymen may be the site of congenital cystic growths.[1] Reported cases of congenital *absence* of the hymen rest upon a somewhat doubtful basis.

VULVA.

There may be absence of the vulva (in monstrosities), or its elements may be slightly developed, or there may be excess of development of the labia or nymphæ, which may be double or triple in number, or they may be quite beyond the usual proportions, or there may be a bifid clitoris (due to arrest of development), or the clitoris may be undeveloped, or there may be union of the greater or lesser labia. This last condition is one of the few abnormalities of the sexual organs which may be detected, and, where the union is superficial, may be easily operated upon during infancy or early childhood: failure to separate the labia by early surgical interference may result seriously in adult life (difficult coitus and parturition). A combination of some of the above features—viz., large bifid clitoris, with union of the labia up to a point which will just allow of exposure of the clitoris (thus simulating a scrotum), with hernia of ovaries into the labia—gives an appearance of female hermaphrodism. There may be a cleft in the anterior wall of the urethra (*epispadias*) or in the anterior wall of the bladder (*extroversio vesicæ*), or a deficiency in the posterior wall of the urethra (*hypospadias*). These abnormalities, together with the subject of hermaphrodism, are considered elsewhere in this volume.

ANOMALIES OF COMMUNICATION.

If at that period of embryonic life at which the hollow organs of the genito-urinary system together with the rectum communicate with a common cloaca there is a partial or complete arrest of development, the result is seen after birth in anomalies of communication, to which belong the congenital recto-vaginal, uro-vaginal, and uro-recto-vaginal fistulæ. Any of these abnormal passages may be associated with an imperforate rectum or anus. Imperforation of the vagina may exist with an opening between the vagina and the rectum allowing in after-years of the escape of the menstrual fluid through the anus. In a case which came under the observation of the writer the septum which separates the rectum from the sinus uro-genitalis, and which is completed in the tenth week of embryonic life, had never been developed, and as a consequence the rectum opened into the vagina and the anus was marked by a simple pitting of the skin. In another case of imperforate anus the rectum opened just within the fourchette. These and other abnormalities are much more clearly made out in the adult, because of the larger size of all the parts which enter into the deformity.

[1] Archiv f. Gynäkol., 1884, vol. xxiii. p. 427.

EXCESS OF DEVELOPMENT.

Under the above head may be classed the rare cases of very early sexual development: this excess in growth usually corresponds with precocious menstruation, this function having been established in some instances at a very early period of the child's history, and even, it is stated, in the new-born. One of the most interesting cases of early sexual development is that reported by Dodd,[1] of a girl who began to menstruate at twelve months of age and who became pregnant during her ninth year, being delivered of a child weighing seven pounds, and this, too, after a labor which was not difficult. There was a profuse growth of hair in the axillæ and on the pubes, and the breasts were well developed and secreted a good supply of milk. Another reported case of pregnancy, with abortion at the end of four weeks, in a child aged eight years, seems to be authentic.[2] Dr. A. Vander Veer[3] reports the case of a girl who began to have a regular menstrual flow at the age of four months. Dr. Cortejarena calls attention to the fact, as illustrated by a case reported by himself, that the mental and moral development does not necessarily correspond with the physical evolution.[4]

ABNORMALITIES OF THE MAMMARY GLANDS.

The most frequent abnormalities of the mammary glands are included under the two heads of supernumerary mammæ (*polymastia*) and supernumerary nipples (*polythelia*).

---

[1] Lancet, April 9, 1881, p. 601.

[2] Journal des Sciences Médicales, No. 5.

[3] American Journal of Obstetrics, September, 1883.

[4] El Siglo Médico; Le Réveil Médical, 1880, p. 202.

Rudimentary mammæ and nipples were at one time considered to be of extremely rare occurrence and to be confined in the majority of cases to females, but, thanks to Leichtenstern[1] and others, both of these opinions have been greatly modified. Leichtenstern estimates (this is only an estimate, and not an accurate calculation) the occurrence of supernumerary nipples and mammæ, taking the two sexes indiscriminately, to be one to five hundred. Dr. J. Mitchell Bruce[2] found in a series of cases including both sexes, examined by himself, that the abnormality occurred in more than seven out of one hundred cases. The mistaken belief in the greater frequency of the anomaly in the female than in the male, together with its explanation, has received consideration by Leichtenstern and subsequently by others. The mammary gland being rudimentary in boys, and hence not assuming functional activity, it is not strange that many cases are overlooked; even in girls the anomaly may not be noticed or even suspected until, the function of lactation being established, the presence of a secreting gland in an abnormal situation for the first time attracts attention. It is not always noticed even in the first pregnancy, cases being recorded in which it is asserted that the anomaly was not observed until the sixth or seventh pregnancy.[3]

A systematic observation of a series of persons of both sexes, such as that undertaken and reported by Dr. J. Mitchell Bruce, establishes the fact that supernumerary mammæ and nipples are of even more frequent occurrence in boys than in girls. He makes the following record. In one hundred and four females there were five cases, or four and four-fifths per cent., of the abnormality, and in two hundred and seven males there were nineteen cases, or nine and one-tenth per cent. Leichtenstern collected from literature ninety-two cases: of these there were twenty-two males and seventy females. Of the thirteen cases observed by himself there were nine males and four females.

The usual situation of supernumerary nipples is below the level of the normal nipple and nearer the median line. When the abnormality is single, it is in the majority of instances found on the left side: the explanation of this is not well made out, but it is interesting in this connection to note the fact that it is the left breast which is, as a rule, more developed than the right. Hyrtl accounts for this latter condition on the ground that the left breast is commonly more used during lactation than the right, because of the greater facility with which the child is held upon the left arm, allowing the right to remain free: this is an illustration of what Darwin would style the "inherited effect of use." On the other hand, when there is unilateral amazia, or when with the normal number of breasts one is less fully developed than the other, the anomaly in either case, according to Leichtenstern, is on the right side. When supernumerary glands or nipples appear *above* the normal, they are outward as well as upward; but their presence in this situation is extremely rare (four cases, according to Dr. J. Mitchell Bruce).

[3] On a Case of Secretion of Milk from the Right Axilla, by Charles J. Hare, M.D., etc., Lancet, 1860, vol. ii.

Four is the abnormal number of glands or nipples most common; there may be three, still more rarely five, and Alexander[1] records a case of six nipples.

The *axilla* is one of the rarer sites of this anomaly, Leichtenstern recording five such cases and Bruce none. Such a gland may have a nipple,[2] or there may be a minute orifice not larger than one of the sweat-ducts (as in the case already noted as reported by Dr. Hare), or, as witnessed of course only in adult life, the milk may exude from several minute orifices,[3] in which respect these glands resemble the axillary glands of the monotremata. Usually the supernumerary glands are entirely separate from the gland proper, but exceptionally they appear to be prolongations of the mammary gland, being connected with it by a cord. Such a case was observed by M. Notta.[4] In fifteen post-mortem examinations M. Notta found only one case in which there was an axillary prolongation of the breast in the shape of a cord.

Leichtenstern denies the possibility of the presence of supernumerary breasts and nipples upon the abdomen, but Bruce claims that in more than one instance observed by himself the abdominal wall was the seat of the abnormality. Other locations, according to Leichtenstern, are the back (two instances), the acromion (one instance), and the outer side of the thigh (one case).

J. Bland Sutton[5] quotes from Ahfeld's "Missbildung des Menschen" a case of supernumerary mammæ upon the labium majus. Barth,[6] of Berlin, tells of a girl who while under treatment for another trouble asked to have a wart removed from her face. This growth, of which a detailed account is given, was situated just below the origin of the lobe of the right ear, and was congenital. It was surrounded by an areola of pigment, and it increased in size during menstruation. After removal it was exhibited before dissection to many physicians, who declared it to be a nipple, and microscopic study confirmed this opinion.

[6] Virchow's Archiv, Bd. cxii. S. 569.

Bruce gives a critical analysis of the several cases seen by himself with reference to the degree of development of the gland, the areola, the number of hair-follicles, etc., but it is only necessary to say that the supernumerary gland is usually much smaller than that in the normal situation, and that in the cases reported all grades of development of the nipple have been noted, from those doubtful cases the real nature of which it is difficult to determine unless lactation supervenes, up to the fully-developed and destined-to-be-functionally-active papilla with its well-marked areola.

There is a deformity which in adult life interferes with the performance of its function by the breast, and which may be traced to embryonic development and may show itself even when there are the normal number of breasts. According to Leichtenstern, when the human embryo is seven and a half centimetres in length a single furrow appears in the superficial layer of the skin, and at this early stage in the life of the embryo there exists neither areola nor nipple, nor are milk-ducts present. The milk-ducts (according to the same authority) when first observed in the embryo are ten centimetres long, appearing later in communication with the pre-formed papillæ which out of the original furrow in the skin have gradually been elevated. If the development is arrested, so that the embryonal skin-furrow does not rise into a complete papilla, then in the adult the nipple retains its original embryonic form, appearing as a "quite low prominence, superficially flattened, with a linear cleft in the middle like an os uteri."

There are very few cases in which heredity can be traced. Leichtenstern could trace inheritance in none of the cases observed by himself and in only seven of those recorded in literature. Among the latter is the case in which a woman who had three mammary glands, one on the left and two on the right side of the chest, bore a daughter who also had three mammæ, two in the normal situation, and one, well formed, upon the outer side of the left thigh, a few inches below the great trochanter; this third mamma during childhood was thought to be a mother's mark, but in adult life it, in common with the other two glands, furnished an abundant supply of milk. This is the famous case so often misquoted as a case of inguinal mammary gland.

Alexander (already referred to) tells of a mother and several children all of whom, except one brother, possessed supernumerary pectoral nipples.

Amastia is exceedingly rare. An interesting case of absence of one breast is reported by Paull.[1] In this case the mother became acquainted with the absence of the left breast in the person of her child about three weeks after its birth, the nurse being loath to inform her before. The circumstance was then told to her surgeon, who gave it as his opinion that the breast might be developed at the age of puberty. The mother attributed the defect to her having been frightened during the third month of pregnancy by a woman who called at the door and exposed marks left by the removal of the left breast for cancer. Since it has been stated that cases of partial or complete absence of one or both breasts are usually associated with some other developmental defect, it is interesting to follow the subsequent history of this infant. She was attended in her first confinement (showing activity of the sexual organs) at the age of twenty-two. The writer states, "On examining the case I could not find the slightest trace of the [left] gland, the ribs being in fact less covered than usual, in consequence of the imperfect development of the pectoral muscle. A small pimple represented the nipple. During her pregnancy this rudimentary nipple had increased in size and had become very painful. With the exception of a slight narrowness of the chest, she was well formed."

---

[1] Total Absence of Left Mammary Gland from Non-Development, by Frederic Paull, M.R.C.S., in a letter to the Lancet, 1862, vol. i.

Marandel[1] observed a case of absence of one breast, and Lousier[2] mentions the same deformity in a woman and her daughter. A most interesting case of the entire absence of both breasts, with its accompanying congenital defects, in a boy three and a half years old, is reported by Hutchinson.[3] He had no nipples, and their sites were occupied by little patches of scar. Nothing like a mammary gland could be traced.

Leichtenstern believes that human polymastia and polythelia may be explained as an example of retrogression, and ascribes to every man the latent tendency to produce more than two breasts. While Darwin[4] admits that this theory is greatly weakened by the appearance of supernumerary breasts in unusual situations (such as the back), Leichtenstern says that such exceptions "probably show retrogression to still more primitive ancestors." If we accept the view, which according to Handyside[5] was first brought forward by Laycock, that a mamma is simply an aggregation of highly-specialized sebaceous glands, it is less difficult to understand their appearance in various parts of the body where nutrition is especially active, such as the axilla.

Dr. J. Bland Sutton, in the interesting article already referred to, after a careful analysis of the facts, seems to be justified in his conclusion, which is as follows: accessory mammæ may arise in three different ways,—viz., (1) by atavism, (2) as "sports," and (3), very rarely, by dichotomy.

The writer wishes to express her thanks to Dr. Mary Fisher for valuable assistance in looking up the literature of this subject.

DISEASES OF THE BLOOD AND BLOOD-MAKING APPARATUS.[*]

By J. P. CROZER GRIFFITH, M.D.

DISEASES of the blood and blood-making apparatus constitute a subject so extended and of such scientific importance that the limits of the present article necessitate a discussion of those matters chiefly which possess practical value, and with special reference to features peculiar to the age of childhood.

The characteristics of the blood in children differ but little from those of the blood in adults. In the latter, as in the former, the blood consists of a nearly colorless, alkaline fluid—the plasma—and of corpuscular elements of various forms.

It is usually estimated as equalling $\frac{1}{13}$ of the total body-weight. In children its relative weight is probably somewhat less ($\frac{1}{19.5}$, Welcker),[1] though in the newly-born it is temporarily rather greater. The total weight of the corpuscular elements in adults is estimated by Robin[2] to be about 45 per cent. and that of the plasma 55 per cent. of the whole weight of the blood. The specific gravity is generally stated to be somewhat lower in children than in adults (1045–49 : 1055, Denis),[1] owing to a smaller proportion of solid constituents. This does not, however, apply to the newly-born, in whom there is a specific gravity of 1066, according to Keating and Edwards,[3] and to Jones,[4] who has made careful studies on this subject, finding also at the end of the second week a sudden fall in the specific gravity. The high specific gravity is due to a decided excess in the amount of hæmoglobin. This is the opinion most widely held. The recent researches of Scherenziss,[5] however, lead to a different conclusion,—namely, that the blood of the newly-born is of a lower specific gravity than that of the adult, being deficient in hæmoglobin, though rich in stroma. Krüger,[1] too, believes that there is less hæmoglobin in the blood at birth than a short time later. According to the investigations of Leichtenstern,[2] the amount of hæmoglobin is greatest at or soon after birth, and is least from the middle of the first year to the age of five years, when it again begins to increase. The diminution in hæmoglobin takes place even within the first two weeks of life.

[5] Currier, Ann. Univ. Med. Sci., 1890, ii. L.

The statements regarding the fibrin in the blood of children are conflicting. Of recent writers, Krüger[1] says that the quantity at birth is decidedly diminished, while Silbermann[3] concludes that the fibrin-ferment is increased.

The plasma consists of 90 per cent. water, and contains, besides the corpuscles, albumen; fibrin-forming substance; salts, especially sodium chloride; traces of fat; nitrogenous bodies in small amount, such as urea, uric acid, hypoxanthin, and creatin; traces of certain extractives, as cholesterin, lecithin, sugar, and lactic acid; and gases. The amount of albumen and of salts is generally considered to be diminished in the blood of children, though Scherenziss[4] claims that in the new-born there is an increase of salts.

The corpuscular elements are of four forms: 1. The blood-plaques of Bizzozero, or hæmatoblasts of Hayem. 2. The nucleated red blood-corpuscles. 3. The ordinary red blood-corpuscles, or erythrocytes. 4. The white blood-cells, or leucocytes.

1. The first consist of colorless, minute, homogeneous or finely-granular, disk-like bodies, measuring from 1.5 to 3.5 micro-millimetres,[5] occurring isolated, or frequently agglomerated into the so-called Schultze's granule-masses. Their origin and function are still subjects of much discussion, but they are supposed to bear some part in the production of fibrin and the formation of clots.[6] They are by most observers considered to be independent bodies; but in an elaborate paper recently published by Löwit[7] it is claimed that they are only the products of retrograde metamorphosis, the result of a destruction of the white blood-cells or of a precipitation from the plasma. There are probably 250,000 to 300,000 of them in the cubic millimetre of adult blood, but in infants and young children their number may likely be doubled.[5] Cadet,[8] however, found that the number was decreased in the new-born, as twenty-one children whom he examined exhibited an average of only 171,000 per cubic millimetre.

2. The nucleated red blood-cells are found normally in the red marrow, and are probably intermediate forms between the marrow-cells and the red

[8] Hayem, loc. cit.

blood-corpuscles, and, though they are not found in the blood of healthy adults, they are present, according to Ehrlich,[1] in all varieties of anæmia. They occur in that of the fœtus and the young child up to two or three years of age. They consist of distinctly colored discoid bodies, somewhat larger than the ordinary red blood-cells, and containing one or more nuclei.

3. The red blood-cells form by far the largest portion of the corpuscular elements of the blood, and offer much the greatest interest from a practical stand-point. They are pale-yellow, circular, bi-concave disks, without nuclei, and consist of a stroma colored by hæmoglobin. They constitute the means by which oxygen is carried to the tissues. In the adult they vary but little in their size, which is about $\frac{1}{3200}$ inch, or, according to Hayem,[2] 7.5 micro-millimetres. The number found in a cubic millimetre of blood varies considerably even in health, but averages 5,000,000 in men and 4,500,000 in women. Flexible and elastic and easily changing their shape under pressure, they at once resume this under normal conditions when the pressure is removed.

The number of red blood-cells in the newly-born is relatively increased,[3] but as the child grows older it gradually falls below normal. Silbermann[4] calls attention to the varying size of the red corpuscles in the newly-born, and to the occurrence of "shadows" (*schatten*), or pale corpuscles deprived of their hæmoglobin.

4. The white blood-cells, colorless corpuscles, or leucocytes are masses of finely-granular protoplasm, exhibiting amœboid movements, containing one or more nuclei, and measuring about $\frac{1}{2500}$ inch in diameter. They bear an important part in inflammatory processes, and have also been claimed by Metschnikoff to have a destructive action upon bacteria, preventing their spread in the tissues. The average number present in a cubic millimetre is from 8000 to 15,000. Their relative number compared with that of the red blood-cells in adults varies, as a rule, from 1 : 350 to 1 : 600–700 (1 : 750, Reinecke),[5] though a decided increase of the number of the white blood-cells over this may exist without constituting any indication of illness.

The blood of children contains normally a larger proportion of leucocytes than does that of adults; the ratio being 1 : 135 up to 1 : 210 from the age of twelve hours up to that of one hundred and fifty days,[6] or, according to Moleschott, an average of 1 : 256 from the age of two and a half up to that of twelve years. Children at the breast possess a greater percentage of leucocytes than do those fed on cow's milk (Demme).

The origin of the red and white blood-cells is not even yet definitely understood. Briefly stated, it would seem almost certain that the white cells are formed in the lymphatic glands and other similar adenoid tissue, while the red cells are developed from the leucocytes, from the nucleated red blood-corpuscles in the bone-marrow, or from the hæmatoblasts.

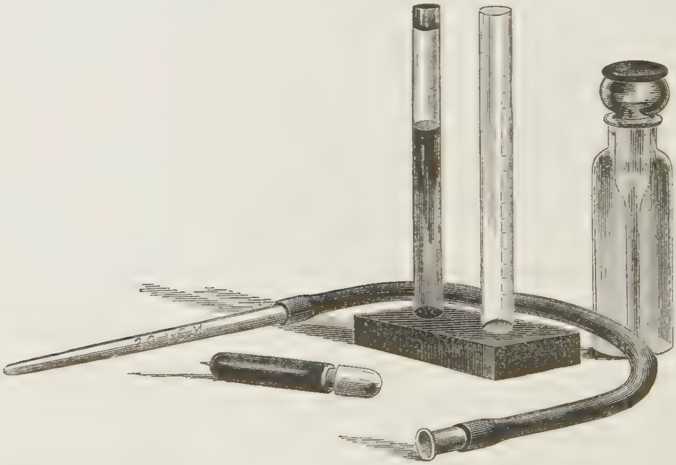
[6] Demme, loc. cit.

In the study of the diseases of the blood and blood-making apparatus, it becomes all-important to understand the most practically useful scientific methods for its examination. Much may be learned from simply viewing with the microscope a drop of blood upon a glass slip. A rough determination can be made of the presence of an increase in the number of the white blood-cells; and the color, shape, and arrangement of the red corpuscles can be noticed, as well as the number of hæmatoblasts and the occurrence of nucleated red blood-cells or of parasites. But for the thorough study of the condition of the blood in disease more exact methods must also be used.

For practical clinical purposes the two important matters to be determined by the employment of special apparatus are the percentage of hæmoglobin and the absolute and relative number of the white and red blood-cells. For the first we may employ the hæmoglobinometer of Gowers or the instrument of Fleischl.

The apparatus of Gowers, shown in Fig. 1, consists simply of a small guarded lancet, a twenty-cubic-millimetre capillary glass pipette, a small bottle with pipette-stopper, and two narrow glass tubes of the same size, one filled with a transparent colored matter which is regarded as the standard, the other graduated with an ascending scale of percentages from 10 to 120. In using this apparatus a few drops of water are first put into the graduated tube, to prevent coagulation of the blood; the finger is then pricked with the lancet, and twenty cubic millimetres of blood are drawn into the pipette and blown into the tube. Water is now carefully added from the bottle, with frequent shakings of the tube, until the color of the

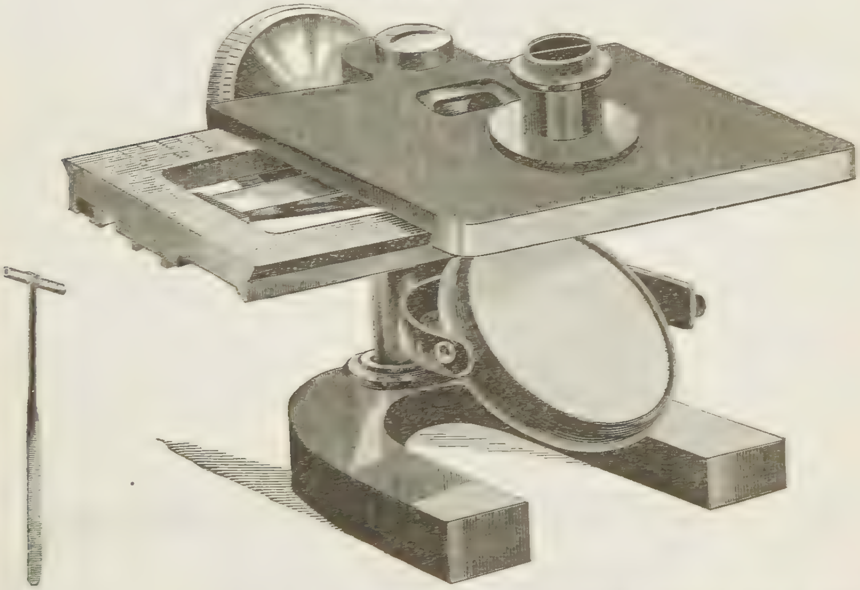
FIG. 1.



diluted blood, both by transmitted light and when held against a white background, is the same as that of the standard. The percentage of hæmoglobin is now read off and recorded. It is evident that the richer the blood is in hæmoglobin the more water will be required to produce a dilution of a color corresponding to that of the standard, and the higher the indicated percentage will be.

Gowers's apparatus is to be recommended for its simplicity as well as on account of accuracy quite sufficient for clinical purposes. A great disadvantage sometimes attending its use lies in the fact that a rather large drop of blood is required to fill the pipette, and that it is sometimes difficult to obtain this in cases of extreme anæmia. Fleischl's hæmometer (Fig. 2) is as accurate and quite as convenient as the instrument of Gowers, and, moreover, requires but a very small amount of blood. The apparatus consists of a small metal table with an opening in the centre, and under this a reflector made of plaster of Paris. The opening is occupied by a small well having a glass bottom and divided into two equal compartments. The most important part of the apparatus consists of a wedge-shaped piece of ruby glass, the more intense color of whose thicker end shades off gradually into the nearly colorless thinner end. The glass is mounted in a carriage moving under the table by a rack and pinion, and on a portion of the carriage, as seen in the illustration, a percentage scale is engraved, the 0 of which is at the same end with the thinner portion of the glass wedge. One-half of the well receives simply the white light from the plaster-of-Paris reflector, while the other rests over the ruby glass and obtains light through it. A small pipette and several capillary glass tubes about three-

FIG. 2.

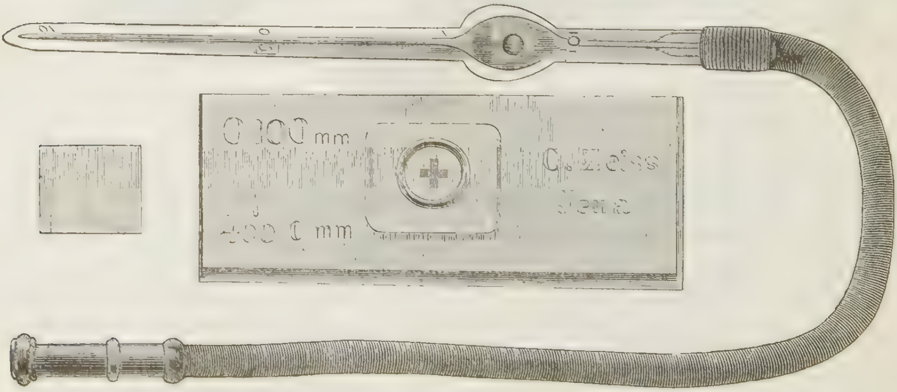


eighths of an inch in length and mounted on slender metal handles accompany the instrument. The tubes are carefully made of such a capacity that the blood contained in one of them, when of the normal richness in hæmoglobin, and when diluted with the proper amount of water in the well, will indicate a percentage of 100 on the scale. To use the instrument, one end of a capillary tube is lowered carefully upon a drop of blood drawn from the finger, whereupon the whole of it immediately becomes filled. The blood is now washed from the tube into one of the compartments of the well, by blowing water through the tube from the pipette. The compartments, which previously contained some water, are now completed and equally filled with it, and the well so placed that the side containing blood receives white light, while the other receives light through the ruby glass. The glass is now moved by the rack and pinion until the intensity of the color in the two compartments is the same, and the percentage is then read off through the small opening behind the well.

I have made comparative tests with these two instruments, and find the readings to be practically the same. Sioling[1] has made careful comparative estimates of the instruments of Gowers, Hayem, Malassez, Bizzozero, and Fleischl, and finds that the latter combines the greatest accuracy with simplicity of method. It should be noted that Fleischl's hæmometer can be used only with artificial light and Gowers's instrument only with daylight. A special tube has been devised to permit the use of the latter at night-time.

For the estimation of the number of red and of white blood-cells several hæmacytometers have been devised, that of Thoma-Zeiss (Fig. 3) being one of the most satisfactory. One portion of this instrument is the "Potain's *mélangeur*," a glass capillary tube with the lower portion graduated to hold ½ and 1 cubic millimetre, and the upper portion widened into a bulbous enlargement of a capacity of 100 cubic millimetres, and containing within

FIG. 3.

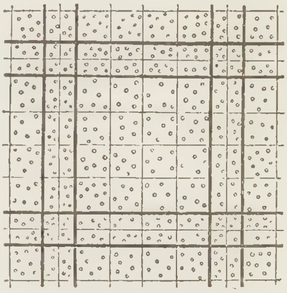


---

[1] Ann. Univ. Med. Sci., 1888, i. 407.

its cavity a small, freely movable glass ball to aid in mixing the blood. The second part of the apparatus is designed for the counting of the blood-corpuscles, and consists of a glass slide on which is constructed a cell exactly $\frac{1}{10}$ millimetre in depth. The periphery of the cell is surrounded by a circular gutter, to prevent the fluid from finding its way between the cover-glass and the slide, as in this event the correctness of the estimation would be vitiated. The bottom of the cell is ruled with intersecting lines forming a large number of squares each having an area of $\frac{1}{400}$ square millimetre. The squares are arranged in larger squares outlined by double lines, and containing 25 of the smaller ones (Fig. 4). A carefully-ground cover-class covers the cell. An easy calculation shows that the cubic space over each small square, between the cover and the bottom of the cell, equals $\frac{1}{4000}$ cubic millimetre.

FIG. 4.



After Jaksch.

To use the instrument the finger of the patient is pricked, and half a cubic millimetre of blood carefully drawn into the pipette. The point of this is quickly freed from all excess of blood, and plunged into a $\frac{1}{3}$ per cent. salt solution, or a 5-per-cent. solution of sulphate of sodium, and the liquid drawn into the bulb until it reaches the mark "101." Meanwhile the tube is constantly revolved between the fingers, in order that the movements of the glass bead may facilitate the thorough dilution of the blood. The mixing being complete, the excess of salt solution remaining in the capillary portion of the *mélangeur* is blown out, and a drop of the diluted blood then placed in the centre of the cell. The cover-glass is now applied, care being taken that no fluid passes between it and the slide, and that no bubbles be present. It is now pressed firmly against the slide until Newton's color rings appear. Lyon and Thoma[1] lay great stress upon this point. Should the rings not develop, it is evidence that there is not good apposition between the slide and the cover; and both must be carefully cleaned and a fresh drop obtained from the *mélangeur*. After allowing about five minutes for the corpuscles to settle, the slide is examined with the microscope under a lens of rather low power, to see that they are evenly distributed, and is then studied with a power of from two hundred to four hundred diameters.

To calculate the number of corpuscles in a cubic millimetre, those are counted which are contained in a series—say 25—of small squares; the corpuscles which touch the upper and left-hand border lines of any given square being considered as belonging to it. A simple equation gives the result,—viz.:

---

[1] Virchow's Archiv, lxxxiv. 131.

$$\frac{\text{Number of times the volume of fluid over one square is contained in a cubic millimetre} \times \text{Dilution} \times \text{Total number corpuscles counted}}{\text{Number of squares counted}} = \text{Total number of corpuscles in a cubic millimetre of blood.}$$

The capacity of the space over each square is, as already stated, $\frac{1}{4000}$ cubic millimetre. Supposing, then, that 25 squares be counted, and that, say, 150 corpuscles be found, the equation would be expressed in figures as follows:

$$\frac{4000 \times 200 \times 150}{25} = 4,800,000$$

As the first three figures of the equation always reduce themselves by cancellation to 32,000, it is an easy process simply to multiply the number of corpuscles in 25 squares by this factor in order to obtain the desired result. Some slips are ruled in squares containing only 16 smaller squares. In this case the factor becomes 50,000. In cases where still greater accuracy is desired, it is better to count many more than 25 squares; and in patients with extreme anæmia one cubic millimetre of blood should be employed instead of half a cubic millimetre.

Although special forms of apparatus have been devised for the determination of the number of leucocytes in a cubic millimetre, the method just described for the enumeration of the red corpuscles may be satisfactorily employed. It is necessary, however, to count a large number of squares in order to attain any degree of accuracy in the result. The fluid used for diluting the blood should be a $\frac{1}{3}$ per cent. solution of acetic acid, as recommended by Thoma,[1] or some solution similar to that suggested by Toison.[2] This consists of distilled water, 160 grammes; glycerin, 30 cubic centimetres; sulphate of soda, 8 grammes; chloride of soda, 1 gramme; methyl violet, 0.025 gramme. The solution should be diluted with an equal volume of water before using. The former dissolves the red cells, allowing only the white to appear; the latter differentiates the leucocytes by staining them.

Various other instruments are sometimes employed in studying the blood, but for purely clinical purposes are not needed or require too great a degree of skill. Among these are the spectroscope, the hæmato-spectroscope of Henoch, and the chromo-cytometer of Bizzozero.

Before taking up the consideration of the more generally recognized diseases of the blood and blood-making apparatus, some attention must be directed to certain of the altered blood-conditions, perhaps more properly viewed as symptoms.

I. Changes in the Morphotic Elements.—A. *Leucocytosis.*—By this title may be designated an increase, usually temporary, in the number of white blood-cells. The ratio of the white to the red cells in this condition may equal 1 : 100 or even 1 : 50, Henry[1] giving the latter figure as its limits. V. Jaksch[2] even claims that the ratio may in children reach 1 : 20 or 1 : 12 without constituting a true leukæmia. In children, as in adults, leucocytosis may be physiological or pathological. The first is witnessed from one to two hours after a full meal, but does not reach the degree seen in the second form. Demme[3] has made careful observations on physiological leucocytosis in infants, and has found a marked increase in the number of leucocytes even within twenty-five or thirty minutes after nursing. Pathological leucocytosis occurs in acute inflammatory diseases, suppurative processes, chronic cachectic conditions, as tuberculosis and cancer, and in many forms of anæmia. Limbeck[4] claims that inflammatory leucocytosis is witnessed only in those diseases in which there exists an exudation somewhere in the body; while in infectious diseases, in which there is none, as intermittent and typhoid fevers, there is no increase in the number of white blood-cells, and in the latter disease even a diminution. Virchow says that all conditions in which the lymphatic glands are involved produce leucocytosis.

---

[1] Virchow's Archiv, lxxxvii. 201.

[2] Jour. des Sci. Méd. de Lille, February, 1885.

Leucocytosis is most apt to be confounded with leukæmia, especially if amyloid spleen or carcinoma in the splenic region be present.

B. *Poikilocytosis.*—This term was first employed by Quincke[5] to indicate a tendency of the red blood-cells to assume variously-distorted shapes, such, for example, as seen in Plate I., Fig. 1. Amœboid processes have also been described.[6] The condition has been supposed to be characteristic of pernicious anæmia, but is not always present in this disease, and may be witnessed in any disorder which is accompanied by marked changes in the blood. Jaksch[7] reports its occurrence in chlorosis, severe anæmias of all kinds, cancer, amyloid degeneration, and leukæmia; and I have rarely seen it to greater advantage than upon one occasion in a severe case of post-hemorrhagic anæmia.

C. *Microcythæmia.*—In microcythæmia, as described by Vanlair and Masius,[8] the blood contains a small or a large number of minute red, globular or discoid bodies containing hæmoglobin and measuring from 1½ to 5 micro-millimetres in diameter. With them are often found red blood-cells of usually large size (macrocytes, megalocytes) but of normal appearance in other respects. These measure from 8½ up to even 15 micro-millimetres in diameter. The diagnostic signification and mode of origin of the microcytes are not definitely ascertained. They are probably either young corpuscles in process of growth, or the remains of corpuscles which have disintegrated. Gräber[1] maintains that neither microcytes nor poikilocytes are present in the circulation, but are the result of changes occurring after the blood is drawn from the body.

It would appear that they are most commonly increased in anæmia, of whatever variety. Osler[2] believes that they are most constantly and abundantly present in the so-called primary anæmias, but especially in pernicious anæmia. They are also found in infectious and toxic diseases.

In the newly-born microcytes are normally found.[3] Demme[4] has found them so numerous in sucklings that the enumeration of the red blood-cells was rendered difficult. He estimates that there are 350,000 to 420,000 in the cubic millimetre at the age of from two to eight days.

D. *Melanæmia.*—This condition, which Pilliet[5] considers more common than is generally supposed, was first described by Meckel[6] in 1847. It is to be regarded as a symptom of melanosis of the organs rather than as a primary affection of the blood, and consists in the occurrence in the blood of granular pigment, generally black, but sometimes brown or yellow. (See Plate I., Fig. 2.) It is either free in the plasma or, more usually, enclosed in the white blood-cells or in other more spindle-shaped or irregularly round cells derived probably from the endothelium of the liver or spleen. The free pigment-granules may be molecular or may exceed the size of the blood-cells. They are sometimes combined with an albuminous matrix into aggregations of various sizes and forms.

The cause of melanæmia is almost invariably malarial poisoning, generally of a severe type; and the pigment is produced by the transformation of hæmoglobin into melanin, through an excessive destruction of the red blood-cells. This destruction takes place either within the blood itself or, more probably, within the spleen, the red bone-marrow, the liver, and the lymphatic glands.

Pigment-granules have also been found in the blood of relapsing fever, and rarely in Addison's disease and in melanotic sarcoma. Soyka[7] has reported melanæmia in a case of extreme anthracosis, in which dark granules of carbon circulated in the blood, and were deposited in the spleen, kidneys, and liver.

II. **Chemical Changes in the Blood.**—To these, other than as already described, only passing reference lies within the province of this article.

Uræmia, which is probably the most important of them, is the term

employed to indicate the presence in the circulation of various substances peculiar to the urine. Which of these is the exciting cause of the symptoms cannot as yet be determined.

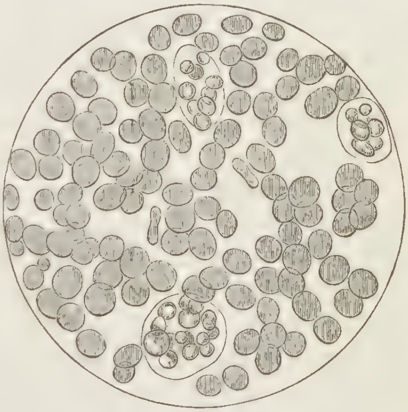
Ammonæmia is a condition but little understood. It is supposed to be a state of the blood caused by the absorption of ammonia, and probably of alkaloidal substances or other products of decomposition, from the diseased mucous lining of the bladder.

Acetonæmia describes that condition in which the blood is laden with acetone. It has been carefully studied by Von Jaksch[1] and others. Though most frequently present in diabetic patients, I have seen two instances occurring in other affections,[2] in which the symptoms seemed to be due to acetonæmia. Tuczek[3] reports the occurrence of acetone in the urine, and of symptoms probably due to acetonæmia, in a child of four years, in whom antipyrin had been used for pertussis.

Cholæmia denotes the presence in the blood of the constituents of the bile, especially of the biliary acids. These acids appear to be the active toxic agents, retarding the pulse, and even destroying the red blood-cells. By delicate chemical processes small amounts of the biliary acids can be found in the blood in cholæmia.[4] The biliary coloring-matters can be detected more easily.[5]

Lipæmia is the term used to indicate the presence of a considerable amount of fat in the blood. The minute fat-globules occur free in the plasma, and frequently are contained within the white blood-cells also. The condition develops physiologically to a slight degree during digestion. It has also been witnessed[5] in chronic nephritis, diabetes, injuries of the bone-marrow, and chronic alcoholism. I have myself seen in a case of ulcerative endocarditis in a male adult an exquisite example of a form of lipæmia in which fat in large quantities was present within the greatly enlarged white blood-cells, although there was none free in the plasma. The somewhat diagrammatic illustration of these is taken from a photograph of the blood of this patient, made for me by Dr. George A. Piersol. (See Fig. 5.)

FIG. 5.



Hæmoglobinæmia is that condition of the blood in which hæmoglobin is circulating free in the plasma. If a certain amount of blood be removed from the body—as by wet-cupping—and allowed to stand for some hours, the fluid above the clot which forms will be transparent but of a red color if it contain free hæmoglobin. In normal blood the serum is transparent and of a yellow color. The presence of hæmoglobinæmia is not by any means always evinced by the occurrence of the hæmiglobinuria. As Ponfick has shown,[1] the liver is able to dispose of a certain amount of the hæmoglobin, converting it into bile-pigment, and producing an unusually rich bile, and fæces of a dark-brown color. When the amount of hæmoglobin exceeds this, it passes through the liver and appears in the urine. Silbermann[2] says that there is physiologically a hæmoglobinæmia in the new-born, as shown by the presence of bile in the urine, and by the occurrence of "shadows" (*schatten*) in the blood. The cause of hæmoglobinæmia is any agent operating to produce a destruction of the red blood-cells within the general circulation, such as the intravenous injection of certain substances, as glycerin, water, blood from other animals, or the occurrence of severe attacks of some of the infectious diseases, etc. Infectious hæmoglobinæmia of the newly-born, the so-called Winçkel's disease, is more conveniently discussed as a distinct affection under Diseases of the Blood.

[5] Von Jaksch, Klin. Diagnostik, 1887, 45.

Among other alterations in the chemical constitution of the blood are the presence in it of a large amount of *peptone*, as indicated in some cases by peptonuria; *mellitæmia*, or the presence of increased quantities of sugar, as seen chiefly in diabetes; the development of *methæmoglobin*, resulting from the poisonous action on the blood of such substances as acetanilid, phenacetin, chlorate of potassium, pyrogallic acid, permanganate of potassium, nitrite of amyl, nitrite of potassium, etc. In addition may be mentioned the occurrence of considerable quantities of *uric acid* in the blood of gouty patients, and *lipacidæmia*, signifying blood containing small amounts of fatty acids.

III. **Parasites in the Blood.**—Some of the vegetable parasites present at times in the blood are found much more frequently in other parts of the body. The *Bacillus tuberculosis* has been occasionally seen in it in cases of general miliary tuberculosis, though in very small numbers. Weichselbaum[3] was the first to observe it in this situation. The *Bacillus anthracis* is not infrequently present in the blood, and that of *glanders* and of *typhoid fever* has also been discovered there.

One of the most interesting of the micro-organisms in this connection is the *Spirillum Obermeieri* or *Spirochæte Obermeieri* of relapsing fever, first discovered by Obermeyer.[4] (See Plate I., Fig. 3.) It is generally described as a distinct species, though classified by Sacheroff[5] as only one stage in the development of a large hæmatozoon. The spirillum consists of a very slender spiral filament, from 16 to 40 micro-millimetres in length, which exhibits very active snake-like movements in the direction of its long axis. It can be found in the blood only during the febrile stage of the disease. Even with a lens of low power a certain disturbance may be noticed among the red blood-cells, due to the movements of the parasite. Its structure seems to be entirely homogeneous. It is exceedingly sensitive to and easily killed by different reagents, but may be kept alive for days in blood, or in a one-half per cent. salt solution. A cover-glass preparation of blood containing it may be best stained with fuchsin. For a discussion of relapsing fever, see the article by Curtin in this Encyclopædia.[1]

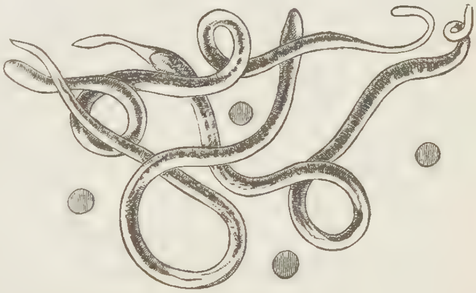
[5] Rev. Scientif., July 6, 1889, quoted by Henry in Ann. Univ. Med. Sci., 1890, vol. ii. E.

The peculiar *Plasmodium malariæ*, which has awakened so great interest, is fully described, with illustrations, in the article on malaria contributed to this Encyclopædia by Forchheimer.[2] I have repeatedly witnessed its various forms in the blood of malarial patients, and even based a diagnosis upon its presence.

Of animal parasites, the *Filaria sanguinis hominis*, as seen in the blood, is the embryonal form of a nematoid worm. The larva was first discovered by Wucherer[3] in the urine, and afterwards by Lewis[4] in the blood. (Fig. 6.) It is $\frac{1}{70}$ inch in length and $\frac{1}{3500}$ inch in thickness, and is provided with a blunt head and a long pointed tail. Mackenzie[5] calculated that from 36,000,000 to 40,000,000 were present in the circulation in his patient at night. They can be found, in fact, only about the time of day during which the patient is at rest in bed.

FIG. 6.



A few red blood-corpuscles are introduced to show relative size of parasites. (After Lewis.)

The parent worm (*Filaria Bancrofti*) is from three to four inches long, and about as thick as a hair. It has been found in the larger lymphatic vessels in a few cases. The embryos may remain a long time in the human body without doing damage, but may finally, by bursting through the blood-vessels, give rise to hæmaturia or chyluria. Though indigenous to the tropics, the parasite has been discovered by Guitéras[6] in the blood of a patient who had never left the United States. It is probable that mosquitoes draw into themselves the larval filaria with the human blood. This then develops within its host, reaches the perfect form, is deposited in water by the insect, and is ingested by man, to again produce larvæ within him. The parasite exists in children as well as in adults; in fact, the second autopsy made by Lewis was in the case of a young girl of sixteen years.

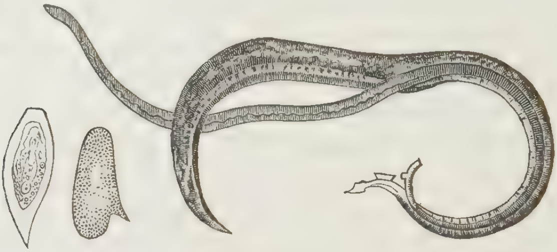
[6] Medical News, April 10, 1886.

The *Bilharzia hæmatobia*, or *Distomum hæmatobium*, a trematode worm, was discovered by Bilharz.[1] (Fig. 7.) It is of very frequent occurrence in Egypt, and is particularly liable to develop in males, and especially in boys. The male is a thread-like worm about half an inch in length, somewhat flattened, and provided with a channel into which the female is received. The female is thinner, and about three-quarters of an inch long. The parasite is present in the veins of the portal system, especially the small ones of the rectum, bladder, ureter, and pelvis of the kidney. It is not found in the general circulation. The eggs are very numerous in the vessels of the bladder and pelvis of the kidneys, and may usually be observed in the bloody urine.

FIG. 7.



After Leuckart.

CLASSIFICATION.

The classification of the diseases of the blood and the blood-making organs presents many difficulties. Apart from the constitutional diseases, as already described in vol. i. of this work, and from malignant and surgical affections of the hæmatopoietic system, treated of in vol. ii., the following provisional classification may be made: 1, Plethora; 2, Anæmia of various forms; 3, Addison's disease, which by some writers is included among disorders of the blood-making system; 4, Infectious hæmoglobinæmia of the newly-born (*Hæmoglobinæmia neonatorum infectiosa*),—other forms of hæmoglobinæmia either scarcely meriting the title of distinct diseases or receiving consideration in the department of this Encyclopædia treating of hæmoglobinuria.

---

[1] Zeitschr. f. Wissensch. Zool., 1853, iv. 59, 72, 454.

PLETHORA.

Plethora or polyæmia is a condition in which the total amount of blood in the body is persistently in excess of normal; or in which some of its constituents, especially the red blood-cells, are greatly increased in amount, without any diminution in the volume of the blood.

It is the general opinion at the present time that the first of these conditions does not exist except as a transitory affection. The full-blooded appearance usually described as plethoric may be due in some cases to an abnormally large number of red blood-cells in the circulation, but in other instances it probably depends simply on an irregular distribution of the blood. It is certain, in any case, that even this plethoric appearance is of the rarest occurrence in childhood, in which age a tendency to anæmia physiologically obtains. In the newly-born, however, there may probably be immediately after birth a state of absolute plethora, due to the passage of some of the blood from the placenta into the body of the child. Independently of this, the blood at this age exhibits a relative plethora, a polycythæmia; being unusually rich in red blood-cells. In one of a series of newly-born infants examined by Henry[1] the number of corpuscles equalled 6,410,000, and in another 5,925,000, per cubic millimetre. Cadet[2] found the mean of his estimates of the red corpuscles of the newly-born to be 5,696,000, the highest figure being 6,920,000; while the average of the results obtained by Demme[3] gave 5,650,000 to 5,860,000 in one cubic millimetre. Hayem[4] has shown that the number depends on the time at which the umbilical cord is tied. Thus, in six children in whom the ligation was made immediately after birth, the average equalled 5,087,000; while in eight others in whose cases it was delayed until all pulsation had ceased, the average was 5,576,000 per cubic millimetre.

This condition of plethora, however, disappears very rapidly, as was shown by the observations of Henry. In the first case quoted above, the number of corpuscles was reduced in twenty-four hours to 5,810,000, and in two days more to 5,680,000.

The term "hydræmic plethora" is sometimes employed, instead of the better title "hydræmia," to express that condition in which the loss of red blood-cells or of albuminous matter has been supplied by water. It does not indicate any actual increase in the total amount of blood in the body.

A relative increase in the number of red blood-cells does not of itself constitute plethora. The amount of fluid in the blood must not be diminished. If this has occurred and is accompanied by the relative increase in the number of erythrocytes, we have to do rather with an "anhydræmia,"—an inspissation of the blood. Such a condition may be observed whenever the body has suffered a great and sudden loss of fluid, as in cholera.

ANÆMIA.

Anæmia may be briefly described as a diminution of the amount of blood *in toto*, or of its albuminous material, red blood-cells, or hæmoglobin. The diminution simply of the amount of water in the blood, as seen in cholera, does not constitute anæmia.

Various titles have been employed to define it; as, oligæmia, oligocythæmia, spanæmia, oligochromæmia, etc.

There is perhaps no pathological condition more frequently observed in children. Children, indeed, after the first few days of life become physiologically anæmic; the blood being hydræmic, with hypalbuminosis and oligocythæmia, and a consequent diminution in the amount of hæmoglobin. Then, too, owing to the ease with which the blood, as well as the other tissues of the growing child, is affected by outside causes, there is scarcely any disease to which children are subject which, if long continued, will not produce anæmia; and often this condition is one of the earliest symptoms. It is, therefore, of paramount importance that every case of anæmia in the early years of life be investigated with particular care as to its cause.

I have found the following classification of the anæmias useful for the purposes of study, though our limited knowledge of the physio-pathology of the subject renders any classification only provisional.

- Anæmia.
  - Non-cytogenic.
    - Hæmolytic
      - Pernicious anæmia.
      - Other toxic anæmias.
      - Parasitic anæmias (some forms).
    - Oligocythæmic.
      - Parasitic anæmias (some forms).
      - Post-hemorrhagic anæmia.
      - Anæmia from loss of albumen.
      - Anæmia of malnutrition.
    - Oligochromæmic
      - Chlorosis (?).
  - Cytogenic.
    - Oligochromæmic
      - Chlorosis.
    - Leucocytic
      - Leukæmia.
        - Splenic.
        - Lymphatic.
        - Medullary.
    - Non-leucocytic
      - Simple constitutional anæmia.
      - Splenic anæmia.
      - Lymphatic anæmia (Hodgkin's disease).
      - Pernicious anæmia (?).

The term cytogenic is used here to indicate those forms of anæmia apparently due to an organic or functional affection of the blood-making apparatus, non-cytogenic applying to those in which some other cause seems to be the operative one. The terms *primary* and *secondary* should either be avoided altogether, or strictly limited in their application. "Primary" applies to the cytogenic anæmias and indicates a primary disorder of the blood-making apparatus, while "secondary" and "symptomatic" appertain, for the most part, to the non-cytogenic anæmias. In one sense, of course, every anæmia is secondary, being itself a symptom; for, as Hayem forcibly insists,[1] the blood is not to be considered apart from the different parts of the body which exert an influence upon its anatomical constitution. From another point of view every anæmia is cytogenic, in that the blood-making organs do not produce sufficient blood to meet the extra demands made upon them by wasting diseases, hemorrhage, excessive destruction of blood, etc.

With our advancing knowledge it seems to become more probable that there are no sharply-defined distinctions between some, at least, of the different varieties of anæmia. Chlorosis is usually viewed as a distinct variety of anæmia, yet cases have been reported by Henry[2] and by Trechsel[3] in which a transition from chlorosis to pernicious anæmia appeared to have taken place; and Henry[2] asserts that the reverse often occurs. It is extremely doubtful, however, whether these are not instances of chlorosis complicated by pernicious anæmia.

Leukæmia, which is generally considered to be a distinct disease, was claimed by H. C. Wood[4] to be nearly related to or perhaps identical with Hodgkin's disease; while Fleischer and Penzoldt,[5] and quite recently Mosler,[6] have reported cases in which there occurred a transition from the latter to the leukæmic affection. The position of pernicious anæmia pathologically is not even yet exactly determined, while clinically it is certainly nearly allied to some other forms of severe anæmia, and sometimes cannot be distinguished from them during life. Musser,[7] for example, reports a case of pernicious anæmia which would at one period have been more properly designated leukæmia, and cases showing the reverse of this have been published by Litten[8] and Leube and Fleischer.[9] Other authors have shown that many cases which once would have been designated essential or idiopathic pernicious anæmia were really instances of secondary forms due to intestinal parasites, atrophy of the gastric tubules, or some other cause.

NON-CYTOGENIC ANÆMIAS.

By far the most common forms of anæmia in childhood are those constituting the non-cytogenic group. They may be subdivided into several classes, some of the members of which shade into one another.

The class of hæmolytic anæmias include those forms which are due to a destruction of the blood within the circulation. "Oligocythæmic" expresses the prominent characteristic of all the members of the second class, though it applies equally well to the first. It is used, however, to designate the characteristic difference between these and the single member of the oligochromæmic class, chlorosis.

Pernicious Anæmia might well be described as the first of the hæmolytic anæmias, in which division I believe that it belongs. It has, however, usually been regarded as an anæmia due to defective hæmogenesis, and its true nature is even yet determined with so little certainty that I have reserved it for the separate consideration which its importance demands.

Other Toxic Anæmias constitute a somewhat heterologous group of cases, some of which could better be described under other non-cytogenic forms. The poison circulating in the blood and exerting its deleterious action may be either (*a*) produced within the body or (*b*) introduced into it from without.

(*a*) It is probable that the anæmia seen in all prolonged febrile conditions belongs to this class, and that it is due to the direct destroying action on the corpuscles of a chemical poison generated by the pyrexia itself. That this is the only cause of the anæmia of fever is, however, by no means certain, as it is possible that the function of the blood-making organs may be directly interfered with, or that the imperfect absorption of food during fever may produce an anæmia of malnutrition. Gerhardt[1] calls attention to the anæmia sometimes developing in children who are recovering from diphtheria. It is of extreme degree, very rapid in its course, and fatal in a few days; and must be regarded as a peculiar toxic form, as it is too severe to be attributed to fever simply or to inanition.

(*b*) Among the inorganic toxic agents introduced into the body from without may be mentioned mercury, arsenic, lead, phosphorus, etc., the first of which is especially apt to be met with as a cause of anæmia in children. Certain of these substances probably produce anæmia in other ways than by a hæmolytic action, while others are directly destructive to the blood-cells. It is an important fact that a prolonged course of mercury carried out in the treatment of constitutional syphilis may itself be productive of profound anæmia. Chlorate of potassium is a well-recognized cause of destruction of the red blood-cells within the body, and other substances, among them the antipyretics, and especially pyrodin,[1] have been shown to have a deleterious action on the blood.

---

[1] Lehrbuch d. Kinderkrankheiten, 1881, 151.

PARASITIC ANÆMIA likewise includes a variety of forms, some of them hæmolytic, others not.

(*a*) Chief among them is the anæmia accompanying malaria, which would appear to be due to the immediate hæmolytic action of the *Plasmodium malariæ* upon the red blood-cells, though our knowledge is not yet sufficiently extended to entertain a positive conviction of this. Malarial anæmia may, on the other hand, be classified as an anæmia of malnutrition, due to the constitutional effect of the disease. Or it may be that the greatly-enlarged spleen often seen in chronic malaria is not without etiological influence; though these cases are more properly relegated to "splenic anæmia." The anæmia of syphilis possibly belongs to the group of anæmias due to the hæmolytic action of a microbic parasite.

(*b*) Certain intestinal worms have been found to be the cause of, or at least to be associated with, an anæmia so profound that the patients exhibited all the symptoms of pernicious anæmia, and were, in fact, considered to be examples of this disease. An instance in which the *Bothriocephalus latus* appeared to produce the characteristic symptoms in a child of thirteen years is reported by Schapiro,[2] and other examples are published by Reyher[3] and Runeberg.[4] It is possible that the anæmia here is of a hæmolytic type, being the result of the absorption into the blood of poisonous chemical matters produced by the worm under certain conditions.

It does not, however, seem definitely established that there exists any etiological connection between the bothriocephalus and the anæmia, since the parasite is frequently present in large numbers without producing the slightest evidence of a disorder of the blood.

The *Anchylostomum duodenale*, or *Dochmius duodenalis*, is the cause of the disorder variously denominated Egyptian or African chlorosis, brick-burner's anæmia, Gotthard-tunnel disease, tropical anæmia, etc. This profound anæmia occurs in both young and old subjects, closely resembles pernicious anæmia in its symptoms, and is attributable to the direct loss of blood produced by the suction of the worms. This form of parasitic anæmia, therefore, belongs rather to the post-hemorrhagic type.

A small thread-worm, *Anguillula intestinalis*, and its Rhabditiform embryos have been found in the intestine in vast numbers, producing the "Cochin-China diarrhœa," and the marasmatic and anæmic condition depending on this.

(*c*) The *Bilharzia hæmatobia* and the *Filaria sanguinis hominis* are other worms not situated in the intestinal tract, which may produce anæmia; the latter probably by obstructing the circulation in the lymphatic vessels or by the actual loss of chyle; the former only in severe cases, and probably by the direct loss of blood in the urine. Both of these parasites occur in children as well as in adults. (See Parasites in the Blood.)

[1] Renvers, Berlin. Klin. Wochenschr., 1889, 986.

[2] Zeitschrift f. Klin. Med., xiii. 416.

[3] Deutsches Archiv f. Klin. Med., xxxix. 31.

[4] Ibid., xli. 304.

POST-HEMORRHAGIC ANÆMIA is the first well-defined variety of the second class of cases, apart from certain of the parasitic forms just referred to. It is less frequently seen in childhood than in adult life. Among its causes in children[1] are melæna, hæmophilia, purpura, umbilical hemorrhage, internal hemorrhages occurring soon after birth, epistaxis, cephalohæmatomata, traumata, etc.

ANÆMIA FROM ABSTRACTION OF ALBUMEN from the blood is another form allied in some respects to the preceding. It is well seen in all diseases where this loss has occurred through long-continued suppuration, as in Pott's disease, hip-joint disease, advanced pulmonary tuberculosis, and chronic suppurative processes of other forms. It may also be observed in chronic Bright's disease with persistent loss of albumen in the urine, in cirrhosis of the liver and in heart-disease with effusion of fluid into the serous cavities, in dysentery with profuse highly-albuminous passages, in excessive onanism, in rapidly-growing neoplasms, etc.

ANÆMIA OF MALNUTRITION, or inanition-anæmia, includes by far the largest and most varied number of cases under the non-cytogenic, oligocythæmic forms.

(*a*) Here may be mentioned first of all that seen in simple inanition, the result of insufficient nourishment of a proper sort,—an anæmia of starvation. Many of the so common instances of anæmia and emaciation seen in young children belong to this category.

(*b*) A similar condition results from the imperfect absorption of nourishment, the result of organic or functional diseases of the digestive tract. Among these are probably to be classified those cases described as pernicious anæmia in which a well-marked atrophy of the gastric mucous membrane has been found. Instances of this have been reported by various observers. A feature of anæmia from this cause, too, is that there is frequently an absence of emaciation, as in pernicious anæmia. This absence is, however, by no means seen in all cases. It is very probable that the atrophy may be secondary to the blood-changes in some instances.

Another form of anæmia to be included here is that which develops in severe and long-continued diarrhœa. This is due not so much to the removal of albumen from the blood as to a lack of absorption of the undigested food and the peptones, which are hurried through and out of the intestine by the increased peristalsis.

(*c*) Improper hygienic surroundings, of whatever sort, are common causes of anæmia. A proper amount of oxygen is equally essential with proper food for the perfect condition of the blood, and the anæmias resulting so frequently in children from too close confinement to poorly-ventilated rooms is consequently to be classified here. The pallor so prevalent among the inmates of many homes for children is a good example of the influence of this factor.

---

[1] Jacobi, Archives of Medicine, February, 1881.

(*d*) Perhaps best classified among the anæmias of malnutrition is that seen in congenital syphilis, tuberculosis, rachitis, scrofula, rheumatism, possibly malaria, scurvy, and other constitutional diseases. The pallor may even make its appearance before any of the local manifestations of the general disorder become manifest. In various, and usually unknown, ways the general nutrition of patients with these diseases becomes profoundly altered, and the blood necessarily suffers also. The exact etiological relation of the constitutional affections to the anæmia cannot be positively determined in the present state of our knowledge. It is possible that the diseases influence directly the functions of the blood-making organs, relegating these anæmias rather to the cytogenic type; or that rickets and the extreme anæmia which is often its first symptom are both the effect of a common cause.

Symptoms.—The condition of the blood after a hemorrhage of considerable amount is that of simple oligæmia. which, however, almost immediately changes by the absorption of water into an oligocythæmia, combined with leucocytosis and hypalbuminosis. The fibrin net-work, too, is less marked than in health.[1] In the other forms of non-cytogenic anæmia described its state is very similar, but the amount of fibrin is often increased, and the number of leucocytes but slightly so.[1] The size and shape of the red blood-cells are generally not much altered, except in extreme post-hemorrhagic anæmia, in which poikilocytosis is sometimes quite marked. The diminution in the number of red blood-cells is often very great, though probably never so extreme as is sometimes seen in pernicious anæmia.

The other symptoms of the anæmias which have been discussed must necessarily vary to some extent in different cases, depending on the nature of the cause. In general may be mentioned pallor of the skin and mucous membranes, eventually more or less emaciation, smallness and flabbiness of the muscles if the disease has lasted for any length of time, clubbing of the fingers, irritability of the nervous system, impairment or perversion of appetite, irregularity of the bowels, and imperfect digestion. Indisposition to exercise is often, but not always, seen in anæmia in children. Jacobi[2] calls attention to the fact that babies who cry most of the night are often suffering from anæmia, and that the crying may frequently be prevented by food or stimulant given before they are put to bed. The urine is generally light-colored and of low specific gravity, and there is often incontinence of it even when the child is advanced in years. Some degree of œdema may appear, especially in the feet and ankles. Epistaxis is very frequent. Leucorrhœa attends anæmia in not a few cases in girls even of only two or three years of age. The pulse is small; the heart's action is accelerated; palpitation is frequent. A venous hum can occasionally be heard in the jugulars in children of but two or three years of age, but Bednar[1] never detected it in the newly-born. Anæmic murmurs may often be heard over the præcordium, and not infrequently over the fontanels and in the carotids. Breathlessness and palpitation are sometimes present, but are not common in children.[2] Catarrh of the respiratory passages is liable to develop. In young children anæmia of the brain, perhaps consecutive to a profuse diarrhœa, produces general coldness, semi-stupor, and finally death.

[1] Osler, System of Medicine by American Authors, 1885, iii. 888.

[2] Archives of Medicine, 1881, p. 16.

Pathology and Pathological Anatomy.—The bodies of those who have died in a very anæmic condition exhibit a more than ordinary pallor, while the post-mortem rigor and the cadaveric lividity are generally but little marked. The adipose tissue everywhere is usually much diminished, and œdema and serous effusions may be present. The internal organs are pale, and often decidedly smaller than normal. One of the most characteristic changes in advanced anæmia is the tendency to wide-spread fatty degeneration of the organs, best seen in the heart-muscle and the lining of the large blood-vessels.

It is a noteworthy fact that, contrary to the statement frequently made, the bone-marrow in severe cases of the symptomatic anæmias may exhibit the lymphoid appearance often described as characteristic of pernicious anæmia. Instances of this have been reported by Neumann[3] and others, and the condition has been experimentally produced in dogs by repeatedly bleeding them.

Immermann[4] attributes the atrophy and fatty degeneration to a condition of hypalbuminosis rather than to oligocythæmia, since it is the amount of albumen supplied them upon which the nourishment of the cells of the organs depends. The oligocythæmia is, indeed, a conservative feature, since, on account of it, less oxygen is supplied to the tissues, and the rapidity of their consumption is thereby diminished.

Diagnosis and Prognosis.—The diagnosis of secondary anæmia is the recognition of its cause; and this is a matter of the greatest importance, on which the formation of the prognosis depends.

Treatment.—The treatment consists primarily in that directed against the source of the pathological alteration of the blood. In addition to this, and when not contra-indicated, attention must be directed to the treatment of the anæmia itself. For this purpose iron will be found to be the drug on which the greatest reliance can be placed. Owing to the irritability of the stomach which often exists, it should be given in some unirritating form, as the malate, lactate, citrate, or albuminate.

The administration of a proper amount and sort of nourishment is also all-important, while sufficient fresh air and exercise and the establishment of proper hygienic surroundings are indispensable. Arsenic is a useful remedy, especially in chronic and obstinate cases, and may be given in proportionately much larger doses than adults will bear. Great reliance, too, can be placed on cod-liver oil, either alone or in combination with iron. Strychnine proves useful in some instances, as does phosphorus in others.

CHLOROSIS.

Synonymes.—Chloranæmia, Chloroanæmia, Morbus virgineus, Green-sickness, etc.

Definition.—This form of anæmia, which has been known since the time of Hippocrates, may be classified either as an oligochromæmia of non-cytogenic origin, or, as seems to me more probably correct, as a cytogenic anæmia of peculiar type. It is a variety of anæmia occurring almost exclusively in girls and young women, and characterized by a peculiar greenish-yellow and exceedingly anæmic hue, but without emaciation, by a well-defined oligochromæmia without a proportionate oligocythæmia, by extreme languor, dyspnœa, and palpitation on exertion, and often by cardialgic attacks.

Etiology.—The cause of the disease has been a subject of great dispute. The influence of heredity as a predisposing factor is seen in many cases; the female members of the same family for several generations often becoming chlorotic at the same period of life. There may exist, further, a predisposition resulting from a congenital imperfect development of certain organs. Particularly have claims been made for the influence of an undeveloped state of the uterus and ovaries, but such a defect is by no means constantly present. Virchow[1] in 1872 advanced the theory that chlorosis was due to a congenital smallness of the heart and narrowness of the vessels, as a result of which an insufficient supply of blood was furnished to the digestive and hæmatopoietic organs at the time when the rapidly-advancing growth of puberty demanded the most perfect nutrition. According to this view, the disease is present from infancy, though latent. This explanation has been accepted as conclusive by Baginsky[2] and favorably regarded by many others.

But, though it may apply to many cases, it does not, I think, account for the numerous instances of rapidly-developing chlorosis, nor for the speedy cure usually, and often permanently, produced by the institution of appropriate treatment. Fagge[3] believes that the narrowness is not congenital, but the result of an endocarditis occurring in childhood. Moreover, this peculiar condition is seen in males as well as in females, and has its own characteristic symptoms, not at all characteristic of chlorosis. This has been shown in the cases reported by Fräntzel.[1]

Sex has a strongly predisposing influence, females being those almost exclusively attacked. The disease does, however, appear occasionally in boys, according to the statements of Lund,[2] Nonat,[3] Hayem,[4] and others. The last-mentioned writer has seen it in all the boys in one family.

Age is also an etiological factor. Most cases develop between the ages of twenty-four and fourteen years, though the disease may appear at a period of life much younger than this, as Cantrell,[5] Förster,[6] Becquerel,[7] and others have shown.

Previously existing poor health or the occurrence of some severe malady, also bad hygienic conditions, insufficient food, and unsuitable occupation, are not without etiological significance. The affection appears to be quite common among factory-girls, but by no means spares girls of the upper circles of society. Influences acting upon the nervous system are of great importance: among these may be mentioned psychic disturbances of various sorts, masturbation, excessive mental or bodily labor, etc.

Finally, the establishment of the menstrual function has been largely accredited with the production of chlorosis, though it can certainly not be considered the only factor; and it is difficult sometimes to determine to how great a degree a menstrual irregularity is the cause of the blood-affection, or how far it is the concomitant or the effect of this. This is also the view which Strümpell[8] expresses. I have repeatedly observed cases in which the other symptoms of chlorosis appeared before the diminution in the amount of the menstrual discharge, which had previously always been normal in every particular. Stephenson concludes,[9] from the analysis of 232 cases, that scanty and irregular menstruation is as constantly present in chlorosis as is the imperfect formation of the red blood-cells; but he considers the conditions independent of each other,—not related as cause and effect.

Symptoms.—The symptoms of chlorosis usually develop insidiously, and consist of a more or less well marked yellowish-green, anæmic hue, though the cheeks are sometimes flushed (*chlorosis rubra*); no diminution in the amount of fat, and sometimes even an increase of it; occasionally slight œdema; dyspnœa, palpitation, and a sense of fatigue on the slightest exertion; languor; a tendency to dizziness and fainting; disturbance of digestion, with diminished or depraved appetite, and constipation. Irritability of the nervous system is present, and hysterical convulsive seizures are not infrequent in children.[1] Disorders of menstruation are very commonly present. The heart's impulse may be widened, with evidences of dilatation of the right ventricle. Systolic murmurs may sometimes be heard over the præcordium and in the carotids, and there is usually a well-marked venous hum in the jugular or other veins, which may even be perceived by the patient as a continuous humming sound in the head. The pulse is small and the arterial tension low. The urine is of low specific gravity and light color, and contains a diminished amount of urea and uric acid, and sometimes a trace of albumen, but casts are never found in it.[2] A peculiar pigmentation of the dorsal surfaces of the fingers has been described.[3]

Attacks of gastralgia are usually considered characteristic of chlorosis as distinguishing it from other forms of anæmia, and are probably of a purely neurotic nature and dependent on the alteration of the blood. Förster[4] lays particular stress on the importance of this symptom; and, having shown that in the statistics of a large number of anæmic children it was much more common after the age of six years in girls than in boys, he concludes that this is an indication that the anæmia was really a chlorosis in the case of the former. Other neuralgias, particularly of the trigeminal, are present with greater frequency in older than in younger children.

Fever is certainly of the rarest occurrence in chlorosis, though it has been reported by a few writers.[5] I cannot but believe that it is doubtful whether it ever occurs as an actual symptom of uncomplicated chlorosis. Hayem[6] reports its presence in only two out of seven cases of the disease, in which records of the temperature were taken; and in both of these there was also extreme diminution in the number of red blood-cells,—*i.e.*, an oligocythæmia, if at all a chlorosis.

The state of the blood is of the greatest interest. The most striking characteristic is a marked diminution in the percentage of hæmoglobin. This oligochromæmia, first pointed out by Duncan,[7] is out of all proportion to the reduction in the number of red blood-cells. Oligocythæmia cannot, in fact, be regarded as at all a characteristic of pure chlorosis, and when present—as it, indeed, frequently is—it must be considered a complication. The majority of recent investigations establish that this is one of the most marked features of the disease, and that the disproportion between the reduction of the hæmoglobin and that of the red blood-cells must be present in order to allow of the diagnosis of chlorosis in any case. Gräber[1] found that the number of red blood-cells was not diminished in twenty-eight cases of pure chlorosis, the average being 4,482,000 per cubic millimetre. In all of them, however, the average amount of hæmoglobin was but one-half or one-third of the normal amount. Henry is probably right[2] in refusing to recognize as chlorosis the cases in which Laache[3] found all the clinical symptoms of anæmia but without the blood-changes. Of 13 cases which I have quite recently examined, the results were as follows, the percentages of red cells being based on a normal of 5,000,000 :

[6] Du Sang, 1889, p. 673.

[7] Sitzungsbericht d. Kais. Akad. d. Wissenschaften zu Wien, 1867.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.	XIII.
Percentage of red blood-cells .	69	66.5	81	57.5	80	94	83	55.5	86.4	80	97.6	76.5	80
Percentage of hæmoglobin . .	36	37	35	32	58	51	31	31	39	35	41	29	58

It will be seen that in two cases only was there a decided reduction in the number of corpuscles, while in all the amount of hæmoglobin was much below normal. In the 10th case, which was a typical example of *chlorosis rubra*, the corpuscles had increased to 5,248,000, or 105 per cent., after a month's treatment, but the hæmoglobin had reached only 57 per cent.

The red blood-cells vary greatly in size and form, and numerous microcytes and some macrocytes are often to be seen. Several observers have found the average diameter of the red blood-corpuscles somewhat diminished.[4] The normal relations of the white blood-cells are not essentially affected.

Immermann[5] says that the amount of the plasma and the contained albumen is not diminished in chlorosis, and that this is a distinguishing characteristic of the disease as compared with anæmia ; while Becquerel and Rodier[6] assert that the amount of albumen is even sometimes increased.

Pathological Anatomy.—No characteristic changes are to be found post mortem. The adipose tissue is usually well preserved. A rudimentary state of the uterus and ovaries has been noticed in some cases, and a narrowness of the arterial system with smallness of the heart and excessive thinness of the vessel-walls in others. No change has been detected in the blood-making organs which could explain the cause or the nature of the disease.

Pathology.—We are still greatly at sea regarding the pathology of chlorosis. If, as Zander[7] and Bunge[8] claim, the condition of the blood is due to a defective absorption of iron from the intestine, the nature of the affection would be clear, and we would class it as a non-cytogenic anæmia. Bunge's theory is, that a large excess of the products of decomposition in the intestine, and especially of sulphur, breaks up the assimilable iron and unites with it, thus preventing its absorption. Large doses of the drug are consequently required in order that these substances may be neutralized, after which absorption of iron can begin. Zander is of the opinion that there is a deficiency in the hydrochloric acid of the gastric secretion, as a result of which the iron ingested in the food is not dissolved and rendered assimilable.

[6] Gaz. de Paris, 1844, Nos. 47–51.

[7] Virchow's Arch., lxxxiv.

[8] Practitioner, August, 1881.

These explanations are not satisfactory, for they by no means apply to all cases, notably those in which large amounts of iron are administered without effect, those which recover without treatment or under minute doses of iron, and those which are cured by other plans of treatment than iron or hydrochloric acid, or which prove intractable to all. As there is nothing in the other possible causes mentioned adequately to account for the origin of the disease, we are forced to consider chlorosis a cytogenic anæmia of peculiar form, due to an inability on the part of the blood-making apparatus to produce a proper quality of the blood,—*i.e.*, a primary, defective hæmogenesis. This inability is undoubtedly occasioned to some extent by predisposing causes, but must also in many cases depend largely on some sort of functional lack of energy of the blood-making organs themselves. The classification of chlorosis as a "primary" anæmia is adopted by Fagge,[1] Strümpell,[2] and others.

Various other views regarding the pathogenesis of the disease have been expressed. Gräber[3] believes it to be due to an excessive alkalinity of the blood, and Clark[4] and Duclos[5] are of the opinion that it is a toxæmia resulting from the retention and absorption of decomposing fæcal matter. Henry[6] considers it to be the expression of a general cachexia rather than an affection of the blood merely. He is disposed, too,[7] to deny to chlorosis the characteristic blood-change described; and says that the condition of the blood depends in each case upon the stage of the disease. He agrees in this respect with Hayem,[8] who recognizes three forms or stages of the affection, determined respectively by the number of red blood-corpuscles present. I have already expressed my inclination towards the view that the oligocythæmia, when present, should be regarded as a complicating element, and not as a symptom of chlorosis.

Complications and Sequelæ.—Gastric ulcer is one of the principal complications, though less frequent in children than in adults, and Baginsky[9] believes that it is not uncommonly the cause of the gastralgic attacks. Chorea is often seen in chlorotic children, and its development is perhaps favored by the disease of the blood.[10] Pulmonary tuberculosis appears especially liable to develop in chlorotic patients. Without doubt chlorosis can be complicated by anæmia, and even by pernicious anæmia; and in this way are to be explained the different grades of the disease as given by Hayem and Usac.[1] Virchow says that there exists a strong predisposition to endocarditis in chlorotic patients. Basedow's disease has been stated by Friedreich[2] to be prone to develop in chlorotic girls and women. Vergely[3] has been able to collect a few cases of thrombosis of the veins or arteries, and Huels[4] reports another instance of very widely spread thrombosis.

[9] Lehrb. d. Kinderkrank., 1887, 291.

[10] Förster, Gerhardt's Handbuch, etc., 1877, iii. 211.

Diagnosis.—The diagnosis rests mainly on the characteristic condition of the blood, the occurrence of the disease chiefly in girls at puberty, the persistence of the adipose tissue, and the association with disordered menstruation.

From secondary anæmia chlorosis is to be distinguished by the absence of a definite, discernible cause, and usually of decided emaciation, and by the presence of the characteristic hæmic alteration and the hue of the skin.

From pernicious anæmia it differs in that the relation of the percentage of hæmoglobin to that of the red blood-cells is exactly reversed in the two diseases. There is, further, neither retinal hemorrhage nor fever: in fact, the occurrence of fever in a case reported as chlorosis would render the correctness of the diagnosis extremely doubtful, or would indicate that some complication had arisen.

The œdema and albuminuria sometimes met with in chlorosis are distinguished from those of Bright's disease by the absence of casts.

Prognosis.—Fatal cases the result of chlorosis itself are almost never witnessed. Death is due to some intercurrent disease. Though the duration of the malady is very variable and often much prolonged, most cases yield to appropriate treatment. Relapses are liable to occur in many instances; probably in those in which the vascular anomaly described by Virchow exists. There are certain cases, too, which prove most intractable.

Treatment.—Prophylaxis is of the greatest importance, and must be practised from early childhood. A proper amount of exercise, cold bathing, fresh air, and sunlight, and proper nourishment, especially of an animal nature, must be insisted upon, as well as the avoidance of the summer heat, nervous excitement, and of over-exertion either of the body or mind, and especially of close confinement and overwork in factories or schools. All suitable measures must be employed to remove indications of debility, and to preserve perfect health. The child must, in fact, be made ready to meet the demands of puberty. To combat the disease when present, iron is almost a specific, but must be given persistently. Full doses are recommended by most writers. Blaud's pill is a favorite form in which to administer it. This consists of half an ounce each of carbonate of potassium and of sulphate of iron, divided into ninety-six pills. Three of these may be taken three times a day. Other preparations of iron may be selected, and when there is any digestive disturbance, and particularly where the existence of gastric ulcer is suspected, some entirely unirritating form of it must be employed. Other tonics, such as cod-liver oil or strychnine, will also be found useful as adjuvants. The digestion will frequently need to be carefully regulated, and may require the administration of dilute hydrochloric acid. Hygienic conditions must be carefully looked after, and massage, cold sponging, and sea-bathing are of value. In cases in which there is no catarrhal or inflammatory condition of the digestive tract, and in which iron has proved useless, Schultz and Strübing[1] have obtained good results from the administration of sulphur. Sée[2] gives an almost exclusively albuminous diet, and rarely administers iron. Inhalations of oxygen have also been advised.[3] Antiq[4] obtained the best results with enemata of defibrinated blood.

LEUKÆMIA.

Synonyme.—Leucocythæmia (Bennett).

Definition.—A disease of hæmatopoiesis, characterized by a great and progressive increase in the number of white blood-cells, and a diminution in the number of red blood-cells, with hyperplasia of the spleen and bone-marrow, and often of the lymphatic tissue in other parts of the body.

History.—The peculiar appearance of the blood in leukæmia was observed and described by Craigie and Bennett in 1845,[5] and, indeed, by Velpeau, Piorry, Bichat, Morgagni, Rokitansky, Andral, Donné, and others previously. Virchow,[6] writing a month after Bennett, recognized that the condition was really an increase in the number of white blood-cells, and not due to the admixture of pus with blood, as Bennett had supposed. There seems to be no doubt that he, too, was the first to appreciate the probable connection between this increase and the change in the spleen and lymphatic glands. Fuller and Walshe in 1846[7] demonstrated the change in the blood of living patients, and Vogel[8] in 1849 diagnosed a case during life. Virchow, again, in 1853 divided the disease into a splenic and a lymphatic variety; and later, in 1870, Neumann[1] described a myelogenous form. These three forms are still recognized; and unquestionable instances of pure forms have been reported, though they are rarely found unmixed. The spleen and probably the marrow also are nearly always involved. The lymphatic glands are in most cases but slightly, if at all, affected. Among the earliest reports of the occurrence of cases in children are those of Löschner,[2] Blumenthal,[3] Golitzinsky,[4] and Biermer,[5] and cases have since been reported by various observers.

[8] Virchow's Archiv, iii.

Etiology.—Of the causes of the disease little is known. Heredity, or rather the existence of a family predisposition, has been noticed in a few cases. Casati[6] relates an instance of the disease in a girl ten years of age, whose father and grandmother were said to have suffered from it likewise; Biermer[7] reports the existence of it in two sisters of three and four and a half years respectively, in whose parents no predisposing cause could be detected; Senator[8] saw it in twins of one and a half years, and Eichhorst[8] observed a child of twelve years, as well as her cousin, with the disease. In some instances the existence of syphilis or tuberculosis in the parents appears to have predisposed the children to leukæmia.

Age is an important predisposing factor, since the disease develops in most instances in middle life. It may, however, occur at any period of life, even in infants a few weeks or months old (Hayem,[9] ten months; Fagge,[5] twenty months; Seitz,[10] one year; Mosler,[11] sixteen months; Golitzinsky,[4] two cases, eleven months, and one week; Jaksch,[12] fourteen months; Mayer,[13] sixteen months). Sänger[14] even reports a case of leukæmia in a fœtus still-born at term. According to Baginsky,[15] from 15 to 20 per cent. of the cases are seen in children up to ten years of age; and Gerhardt[16] believes that it is as frequent in childhood as at a later period of life. The predisposing influence of age upon the tendency to the development of any particular form of leukæmia has not yet been definitely determined. I do not know of an instance of the myelogenous variety occurring in a child, unless the case of the girl of seventeen years described by Immermann[1] be included here. Golitzinsky[2] states that the lymphatic form is oftenest seen in children of a few months, and the splenic form more frequently in those of a year or more. Further investigations are needed upon this subject.

Sex, also, appears to be a decidedly predisposing factor, since of 201 cases collected by Birch-Hirschfeld[3] 135 (67.5 per cent.) were in males. Social and hygienic relations may be not without influence, as the majority of the cases occur in the lower and middle classes of society. It is possible, too, that there is a certain tendency to a geographical distribution of the affection.[4]

Of more immediate possible causes, malaria has often been said to exert a powerful influence in the production of leukæmia, and probably does so; but the opinions regarding this matter are very conflicting. The preponderance of medical evidence is in favor of the belief that syphilis, scrofula, and rickets, previously existing in the child, may be etiologically related to leukæmia. The acute infectious diseases cannot be said to be factors of any importance. Leukæmia has in adults sometimes developed shortly after a trauma in the splenic region,[5] and a possible instance of this occurring in a child has been reported by Mosler.[6]

Symptoms.—The disease begins insidiously, and there is no definite order in the appearance of the symptoms. Often the first indication is a progressive failure of health and strength, frequently with more or less irregular fever, while an enlargement of the abdomen becomes perceptible. In some cases bleeding from the nose or the bowels, or diarrhœa and vomiting, may be very early symptoms. Occasionally, too, as in two cases seen by Howard,[7] severe and even fatal hæmatemesis may be among the earliest indications.

Early in the affection enlargement of the spleen may be detected, and is often very considerable and accompanied by dilatation of the superficial abdominal veins. Anæmia, too, usually begins to develop early; and examination of the blood reveals the characteristic change to a greater or less extent, but the spleen or the lymphatic glands may be swollen a long time before this appears. Peculiar and unusual initial symptoms have been reported in children,[8] such as hysterical conditions, pain in the joints, attacks of excitement with loud crying, or dermal hemorrhages suggesting a purpuric state. After the disease is well advanced and the leukæmic cachexia well established, many of the symptoms are simply those of marked anæmia. The child becomes feeble and irritable and indisposed to exertion. The pallor is marked and perhaps slightly icteric, and may rarely be even as intense as in pernicious anæmia. On the other hand, it is not unusual to see a circumscribed flush on the cheeks, even late in the disease. The appetite is generally lost; and, though it be preserved during a long period, as it sometimes is, progressive emaciation is the rule. Pustular eruptions and furuncles may occur, and intense itching has been reported. More or less subcutaneous œdema and effusion into the serous cavities take place in severe cases.

Palpitation, headache, vertigo, ringing in the ears, and attacks of syncope are indications of the presence of anæmia, but dyspnœa is often grèater than can be accounted for in this way.[1] Sleep may be poor, or there may be decided drowsiness and in some instances delirium or coma.

Symptoms of gastric dyspepsia are rarely absent; flatulence is annoying; diarrhœa is a frequent and often fatal symptom, and is particularly liable to occur in children in whom rachitis has preceded the development of leukæmia. There is usually an increased thirst, even when there is no fever. The liver is generally decidedly enlarged, but well-marked icterus is infrequent. There may be evidences of slight bronchitis, or in advanced stages a cough due to pulmonary œdema. Dyspnœa may be further increased by the pressure of enlarged bronchial glands or of the hypertrophied spleen. The heart is sometimes displaced by the pressure of the spleen; a systolic murmur over the apex may be heard. The pulse is rapid and compressible. The temperature in the advanced stages usually exhibits a well-marked elevation, being either intermittent, remittent, or in the worst cases continuously high; and severe chills and profuse sweats sometimes accompany the pyrexia. Deafness has been observed, and has been made the subject of a special study by Gradenigo.[2]

Leukæmic retinitis, first described by Liebreich, is a characteristic of many cases, and may produce decided disturbance of vision. The eyeground is pale, and the veins are tortuous, broad, pale, and of indistinct contour. The arteries are narrow and pale. Scattered retinal hemorrhages are of common occurrence. They are of a bright color, and aggregations of leucocytes are often seen as pale foci in the centre of them.

The urine is usually but little affected, though it occasionally contains albumen and a few hyaline casts. The amount of uric acid is nearly always increased. Hypoxanthin, lactic, acetic, formic, and hippuric acids, and certain other substances, are present in some cases but absent in others, and do not appear to possess any significance. The amount of urea has also been reported increased.[3] Obstinate priapism is a feature not rarely present, as seen, for example, in the case of a boy of fifteen years reported by Edes.[1]

[2] Arch. f. Ohrenheilkunde, 1886, xxiii. 242.

[3] Sticker, Zeitschr. f. Klin. Med., 1888, xiv. 80.

One of the most constant symptoms of leukæmia is the development of the hemorrhagic diathesis, as indicated by the frequent occurrence of retinal hemorrhages already referred to, epistaxis, hæmatemesis, petechiæ or large subdermal hemorrhages, bleeding from the gums, hemorrhage from the bowels, and, rarely, hæmaturia and hæmoptysis. Cerebral hemorrhage may also take place, but less often in children than in adults.

The condition of the blood in leukæmia is a symptom of the greatest importance. When drawn from the finger it coagulates slowly, has a pale and watery appearance, and is sometimes described as of a reddish-brown or even of a chocolate color. The number of red blood-corpuscles is usually reduced, though not excessively, and their proportion of hæmoglobin somewhat diminished. The smallest number of red corpuscles reported equalled 470,000, and occurred in a patient of Sorensen's.[2] They show no great alteration in size and shape, though poikilocytes and microcytes are occasionally seen. Nucleated red blood-cells are sometimes observed in small numbers. Osler[3] describes the number of hæmatoblasts as very variable, and refers also to the readiness with which crystals of hæmoglobin form.

The density of the fibrin net-work is increased, as is also the amount of water, according to the usual view, while the specific gravity is diminished. Sticker,[4] noticing the general fulness and increased tension of the blood-vessels, concluded that in leukæmia a hydræmic plethora existed. On the other hand, the investigations of Bamberger[5] in a case under his care showed that the solids of the blood were increased in amount, and that on this account the plethora could not be hydræmic. The lessened specific gravity of the blood was due to the large number of leucocytes present, the specific gravity of these being relatively low. He, too, has frequently noticed the abnormal fulness of the vessels, but would prefer to designate it by the title "leukæmic plethora." The alkalinity of the blood is diminished.[6]

Lactic and formic acids, hypoxanthin, xanthin, acetic and uric acids, urea, and certain other substances, are found abnormally present or in increased amount in leukæmic blood. Long octahedral crystals, similar to those seen in the sputum of asthmatic patients, were found by Charcot in leukæmic blood. They occur some within and some without the leucocytes, and have been described by White[7] under the name of "leukosin." Damon[8] has described other crystals which were found by him in the blood of a leukæmic boy, and which he named "leucocrystallin."

But by far the most striking of the characteristics of the blood in leukæmia is the increase in the number of the white cells. (Plate I., Fig. 4.) The ratio of these to the red cells increases as the disease progresses, and in advanced cases very commonly equals 1 : 10 or 1 : 5, or may even reach 1 : 3 or 1 : 2, and in a patient seen by Sticker[1] equalled 1 : 0.5. The degree of increase of the white blood-cells which constitutes leukæmia in contradistinction to leucocytosis is variously stated by authors. Gerhardt[2] asserts that the ratio must at least equal 1 : 12, Fleischer and Penzoldt[3] give a necessary ratio of 1 : 20, while Henry[4] places 1 : 50 as the limits of leucocytosis. Osler[5] says that in the same case of leukæmia the ratio may vary greatly at different times, one week being 1 : 8 or 1 : 10, and perhaps the next week equalling 1 : 60 or even 1 : 150. Of course such a ratio as the latter, if constant, would almost exclude the existence of leukæmia.

The leucocytes of leukæmic blood possess certain characteristics distinguishing them from normal blood-corpuscles. Presenting great variations in size, three varieties may be distinguished: 1st. Those about one-half the size of a red blood-corpuscle, with single nucleus surrounded by a thin ring of protoplasm. 2d. A form of the size and appearance of the usual white blood-cell, having two or three nuclei, and with finely granular protoplasm. 3d. A large variety, even twice the size of a red blood-cell, containing three or four nuclei and finely or coarsely granular protoplasm. The first form is, according to Virchow, particularly frequent in leukæmia of the lymphatic type, while the larger cells are most common when the affection of the spleen predominates. The cells of the third class sometimes contain fine fat-globules in their interior, and probably arise in the medulla, and are characteristic of the myelogenous form of the disease.[6] The leucocytes in leukæmia show only sluggish and imperfect amœboid movements, or none at all.[7]

A further characteristic of leukæmic blood, as claimed by Ehrlich,[8] is its color reaction with eosin. Ehrlich describes in normal blood five varieties of leucocytes, depending upon the reaction which their protoplasmic granules exhibit with different reagents. In leukæmia there is, he states, a very marked increase of that variety of leucocyte whose granules possess the property of becoming deeply stained with eosin (*Eosinophilen Zellen*) when treated according to a certain method. In leucocytosis, on the other hand, these cells are diminished in number. Jaksch[9] concludes, as the result of

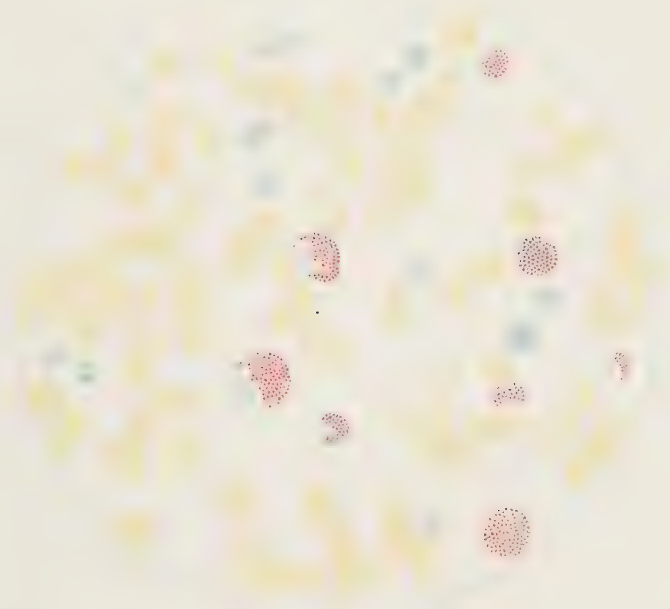
FIG. 8.



BLOOD FROM CASE OF LEUKÆMIA, SHOWING EOSINOPHILOUS CELLS.—Ocular, Zentmeyer A. Objective, Zeiss $\frac{1}{12}$, oil immersion.

his examination of blood in many diseases, that the presence of an increased number of these cells is generally characteristic of leukæmia, though it may very rarely be seen in other conditions.

The method consists in preparing a very thin layer of blood on a cover-glass and drying this at a temperature of about 120° C. for half a day or longer. It is then stained in a concentrated solution of eosin in glycerin, washed in water, dried in the air, and examined in oil of cloves. Huber[1] employs a triple stain consisting of a mixture of indulin, aurantia, and eosin, two grammes of each, in thirty grammes of glycerin. The preparation is stained with this for a half-hour or several days, and washed as before. The red blood-cells by this method should be colored a reddish yellow, and the leucocytes blue; while large leucocytes will also be found which are partly or completely filled with brilliantly stained bright-red granules,—the eosinophilous granules.

Huber's method has not proved at all satisfactory in my hands, and after much experimentation I have adopted the following procedure, with very satisfactory results. The cover-glass preparation of blood is prepared and dried in the way already described. It is then covered for fifteen minutes or longer with a concentrated solution of eosin in glycerin. After being washed in water it is immersed for a second or so in a dilute watery solution of methyl blue, at once again washed in water, dried in the air, and examined in turpentine balsam or xylol balsam. Care must be employed not to overstain with the blue. By this method the red blood-cells assume a color similar to that seen in fresh blood, or a little redder, the leucocytes become blue, and the eosin granules a brilliant red. Plate II., Fig. 8.

As a result of the great increase in the number of leucocytes, the blood coagulates outside of the body into three characteristic layers. The lower red layer, consisting of red blood-cells, is decidedly diminished in thickness as compared with that usually seen, while the middle one, of a milky color and consisting of leucocytes, is of unusual thickness.

With regard to the symptoms of leukæmia pertaining to the hæmatopoietic apparatus, the spleen is in most cases decidedly enlarged, and may extend beyond the median line downward even to the pelvis, and upward into the axilla. Its edge is hard and one or more notches can be felt, and it is generally somewhat painful on pressure. The enlargement produces an evident distention of the abdomen and lower portion of the thorax, particularly on the left side. A rough fremitus can often be detected, and a friction-sound heard over the organ, due to the presence of adhesions; while a bruit synchronous with the pulse is sometimes present. The position which the organ occupies varies in different cases. It moves with respiration, unless held in place by adhesions, and may vary in size at different times in the same case; being sometimes larger after a meal, and becoming much smaller after a profuse diarrhœa or hemorrhage. A diminution in the size of the organ is not always followed by an improvement in the symptoms.[1]

---

[1] Die Path. Hist. u. Bacteriol. Untersuchungsmeth., 1886, 49.

The lymphatic glands are in most cases not much involved, though it is stated that the lymphatic form of leukæmia is commoner in children than in adults.[2] Some swelling of the glands, especially in the neck, may exist for years in lymphatic leukæmia before other symptoms of the disease make their appearance. Then, as in lymphatic anæmia, a more general glandular involvement either slowly or rapidly comes on, and the cachectic state develops. The enlarged glands are usually isolated, not tender on pressure, and not attached to the overlying skin. They vary in size, but most observers agree that it is exceptional to see them as large as in lymphatic anæmia. Leukæmic glands rarely suppurate.

The existence of medullary leukæmia can only be determined with any degree of certainty when swelling, softening, and tenderness of the bones are present, though changes in the marrow may exist without these symptoms. Even the tenderness is by no means an infallible test of medullary leukæmia. This is shown in the cases recently reported by Mayer,[3] in six of which the tenderness existed, though in only two cases was any actual lesion of the marrow found on post-mortem examination.

Pathological Anatomy.—The spleen, which naturally attracts the chief attention, is shown by post-mortem examination to be much enlarged, and may even fill the abdomen to a great extent. An adult spleen weighing eighteen and a half pounds has been reported by Brown.[4] In the early stages it is swollen and soft, the hyperplasia having been confined principally to the pulp, which is of a dark-red color, while the Malpighian bodies are grayish white and not much enlarged. It is at this period that rupture has been known to occur. A more advanced stage, however, is that in which the organ is usually seen. It is then hard, and the capsule much thickened and often adherent to neighboring peritoneal surfaces. It resists the knife, and on cutting it there is seen a great overgrowth of the fibrous tissue of the organ, the reticulum being very abundant and the cells scanty. The section does not look the same in every case. In many it is of a brown-red color and homogeneous appearance, much like that of liver, but sometimes fresh infarcts may be observed, or shining, yellowish or rust-colored patches indicate where previous hemorrhagic extravasations have been. The Malpighian bodies are, as a rule, indistinct or invisible, but more rarely they are hypertrophied and appear as yellowish nodules. The rarity of lymphoid new growths in the spleen is in sharp contrast with their frequency in this situation in lymphatic anæmia.

Enlargement of the lymphatic glands, when present, is probably nearly always secondary to the splenic affection, or at least accompanies it. The glands seldom attain the dimensions seen in Hodgkin's disease, and there appears to be no invariable order in which they become involved, though the internal glands are rarely affected, and those in the neck are oftenest first attacked, especially in children. They may be of either the hard or the soft variety. In the latter they are usually isolated and movable under the skin; although the lymphatic tissue sometimes ruptures the capsule, uniting the individual glands into large masses, or even extending into the surrounding connective tissue. The soft gland exhibits on section a gray or grayish-red color, and contains numerous cells but scanty reticulum, while patches of hemorrhagic extravasation are sometimes seen. The hard gland is often a second stage of the soft variety, but may be hard from the outset. It exhibits an overgrowth of connective tissue, with a thickening of the capsule, and its section is of a gray color.

[4] Lancet, 1877, ii.

The changes in the bone-marrow may be of two sorts, forming the lymphoid and the pyoid marrow, which, however, are probably but different stages in the same process. In the pyoid variety, the one most frequently seen, the normal marrow of all the bones, or of the short and flat ones, is replaced by a yellowish-gray or yellowish-green substance, often much resembling thick pus. This was the condition in the first case studied by Neumann.[1] In the lymphoid variety the marrow becomes grayish red or even deep red in color, and somewhat of a jelly-like consistency. Foci of hemorrhagic extravasation may be discovered in the marrow in some instances.[2] The difference in the two forms seems to depend purely on the degree of increase in the number of the leucocytes, this being enormous in the pyoid form, while but few red blood-corpuscles are to be found. Three forms of cells may be recognized,—large granular ones with distinct nuclei; those resembling ordinary white blood-corpuscles; and small ones like lymph-cells, with large nuclei and a narrow ring of protoplasm. Nucleated red blood-cells are also very constantly found, and Charcot's crystals are very abundant. Cells containing red blood-corpuscles are not so common as in normal red marrow.[3] The bone-substance itself may be either normal, or expanded and spongy.

Of other organs containing lymphatic tissue the thymus gland may rarely exhibit great hypertrophy, as in the case of a boy five years of age reported by Cnyrim.[4] The tonsils may be early much enlarged and ulcerated, and the lymph-follicles of the mouth, pharynx, and base of the tongue affected to such a degree that Mosler[5] has described a leukæmic stomatitis and pharyngitis. A prominent seat of leukæmic change is the intestine, in which the solitary glands and Peyer's patches may present very marked hypertrophy. The cell-growth does not confine itself here to the adenoid tissue proper, but may in advanced cases spread beyond it, forming large projecting and broadly-extending masses, which may ulcerate. The affection of the intestine is often so pronounced that an "intestinal leukæmia" has sometimes been described as one of the primary forms of the disease. Birch-Hirschfeld[1] does not consider this classification warrantable, in spite of the fact that, especially in childhood, leukæmia sometimes develops after intestinal catarrh.

A heteroplastic development of lymphadenoid tissue is not infrequently seen. These lymphomata are lymphoid new growths of local origin, consisting of a delicate reticulum containing leucocytes. They may occur, for example, in the larynx, trachea, bronchi, lung-tissue, pleura, thyroid gland, salivary gland, skin, suprarenal bodies, peritoneum, stomach, pancreas, brain, meninges, and heart. The lymphoid deposits in the retina have already been described. In the mucous membrane of the respiratory apparatus they often strongly resemble miliary tubercles, as was pointed out by Virchow. It is possible for these nodules to reach a considerable size, break down, and form cavities, thus presenting an appearance very like to that of phthisis.[2] Decided enlargement of both lachrymal glands in a leukæmic boy of four and one-half years has been reported.[3] The kidneys at times give evidence of leukæmic disease in the form of a pale-gray, spotted appearance in the cortex and fine gray lines between the rays in the pyramidal portion, while under the microscope are found fatty degeneration of the renal epithelium, a diffuse cellular infiltration, especially about the glomeruli, and a crowding of the capillaries with leucocytes. More rarely distinct lymphatic tumors can be observed.

By far the most common seat of heterologous lymphoid development, however, is the liver. In almost all advanced cases it is decidedly enlarged and is firm on section. The lymphoid new growth is in the form of a lymphatic infiltration, perceptible as a whitish line around the lobules, but penetrating also inward between the liver-cells, displacing and compressing them, and finally producing their fatty degeneration. The lymphoid cells lie partly within and partly around the capillaries. Less frequently large aggregations of these cells are seen, constituting definite, small, grayish-white, lymphoid tumors, the size of a miliary tubercle or larger.

Excepting the hemorrhages often to be found in different parts of the body, the only remaining characteristic post-mortem appearances to be noted are those depending on the condition of the blood within the heart and vessels. The heart usually contains a large amount of clotted blood, especially in the right side; and these clots have a greenish or yellowish color. The blood in the heart may so resemble pus that the impression may be given, as in a case of Virchow's, that an abscess has been opened. Similar clots occupy the larger and smaller veins, and the capillaries throughout the body may be distended with leucocytes. Softening of the brain may result from the thrombosis of the small cerebral vessels with white blood-corpuscles.

Pathology.—The disease consists in a change in the composition of the blood, depending on a hyperplasia of the blood-making tissue. How this change of composition is produced is still an unsettled question. On the theory that the red blood-cells are formed from the white, or mediately through the nucleated red blood-cells, the disease would appear possibly to be a failure on the part of the leucocytes to reach the perfect development of red blood-corpuscles; so that vast numbers of the latter are put forth into the circulation in an imperfect condition,—*i.e.*, as white blood-cells. Leukæmia, then, would be primarily a disturbance of the normal production of red corpuscles. This view is rendered more probable by the fact that not only are the leucocytes increased, but the colored cells are usually diminished in number. As the spleen, the lymphatic glands, and especially the red bone-marrow are usually regarded as the place of the production of the red blood-cells, the cause of the defective corpuscular formation is to be sought for in pathological changes occurring there. Directly connected with this subject is the custom of dividing the disease into splenic, lymphatic, and medullary leukæmia, according as the spleen, glands, or bone-marrow is the primary seat of the disease in certain cases. The question arises whether there actually exist any such different forms, and, if not, which of the three tissues is in reality the one primarily to be affected. Moxon[1] held the view that the spleen is the only starting-point of leukæmia, and that the great number of leucocytes found in the lymphatic glands and the marrow are only secondary deposits from the blood. The view is perhaps favored too by the readiness with which the bone-marrow appears to become affected in various anæmias, even of the non-cytogenic type. It appears to be very probable, however, that the medulla is often the primary seat of leukæmia, Neumann[2] even suggesting that this is the case in all instances. The subject is still very obscure, and needs further investigation.

Pure medullary leukæmia has been reported, but is rare. The combination of medullary and splenic disease constitutes the variety oftenest observed. Next in frequency is lieno-lymphatic leukæmia, consisting usually of a primary disease of the spleen with secondary involvement of the lymphatic glands. The pure splenic form is uncommon, and the pure lymphatic variety certainly rare. The theory has at various times been advanced that leukæmia is a primary disease of the *blood itself*, and that the lymphatic organs are secondarily affected.[3] Sprouck[4] claims that the leucocytes multiply in the circulation by kariokinesis, and compares the process to that going on in a neoplasm. He designates leukæmia "*leucocyphoma sanguinis.*" Bard[1] goes so far as to call it "cancer of the blood." Other writers believe leukæmia to be a specific infectious disease, due to a microbe.[2]

Complications and Sequelæ.—Complications are unusual, the most frequent in children being the occurrence of a low form of pneumonia, which is often fatal. Among other complications occasionally seen are tuberculosis; parenchymatous nephritis; amyloid liver, kidneys, and intestine; fatty or cirrhotic liver; and inflammation of the serous membranes.

Diagnosis.—In well-advanced cases the diagnosis is easy, if the examination of the blood show the characteristic increase in the number of leucocytes. But the ratio of the white to the red cells varies considerably at different times in the same case, and repeated examinations of the blood must therefore be made in some instances. These will probably render the diagnosis clear, except in the early stages of the disease. At this period it may be confounded with leucocytosis, especially if this chance to be attended by a large amyloid spleen the result of suppuration, or by a cancerous mass in the neighborhood of this organ.

It has been stated[3] that one of the differences between leukæmia and leucocytosis consists in the fact that in the former there is, for the most part, a steady increase in the number of white blood-cells, while that of the red corpuscles is correspondingly diminished. In leucocytosis, on the other hand, the number of leucocytes varies greatly at different times, and the inverse ratio of red to white by no means obtains. This is, however, far from being an infallible rule, as shown by the case of Laache,[4] in which the number of red corpuscles was not materially diminished, although the leucocytes stood in the ratio of 1 : 17 with them. The diagnosis is rendered particularly difficult in children by the frequent combination in them of a high degree of leucocytosis with enlarged tubercular glands, or with the hypertrophied spleen of congenital syphilis. Undoubtedly some of the reported cases of leukæmia in children are spurious. Jaksch,[5] indeed, goes so far as to maintain that nearly all of them are so. He claims that there is in children a disease which he names "*anæmia infantum pseudoleukæmica,*" characterized by very decided leucocytosis (1 : 20; 1 : 12) with enlargement of the spleen and lymphatic glands as seen in leukæmia, but without the proportionate enlargement of the liver which he deems a characteristic of it. The prognosis in the two affections is totally different. His observations are of great interest, but have not yet been confirmed and cannot be accepted as conclusive.

[4] Die Anaemie, 1883.

[5] Ann. Univ. Med. Sci., 1890, ii. E; from Wien. Klin. Wochenschr., May 30, 1889.

The views of Ehrlich and of Jaksch regarding the eosinophilous cells afford a valuable diagnostic symptom in distinguishing the two conditions, if further investigations establish the pathognomonic importance of the cells.

Apart from the condition of the blood, leukæmia may be suspected from the existence of irregular pyrexia, progressing emaciation, and enlarged spleen or enlarged lymphatic glands, combined with a tendency to hemorrhage. In young children a rapidly-advancing splenic leukæmia might be confounded with typhoid fever, and the occurrence of intestinal hemorrhage would tend to confirm the mistake.[1]

Leukæmia is further to be distinguished from splenic anæmia, lymphatic anæmia, and sometimes from pernicious anæmia. In the early stages of many cases of leukæmia the diagnosis is of the greatest difficulty, and often becomes certain only when the number of leucocytes reaches a figure which places the nature of the case beyond doubt. Splenic anæmia often presents symptoms exactly similar to those of splenic leukæmia, apart from the difference in the composition of the blood. Hodgkin's disease, too, often closely resembles lieno-lymphatic or lymphatic leukæmia. In the non-leucocytic affection, however, the enlargement is generally much greater and the spleen is not much enlarged. That intermediate or transitional forms probably exist has already been stated. (See Classification of the anæmias.) In the case of the twins reported by Senator,[2] lymphatic anæmia existed for two months before the leukæmic condition of the blood developed.

Finally, it might not be possible to distinguish pernicious anæmia from the myelogenous form of leukæmia if the blood-affection of the latter were absent, and cases have already been referred to in which a transition seemed to take place from the former to the latter affection.

Prognosis; Course.—The prognosis of leukæmia is very unfavorable. Though there may be temporary arrest in its progress, or even improvement in the symptoms, the general course of the disease is onward to a fatal termination. In children the possibility of recovery is perhaps greater than in adults; yet out of thirty-nine cases occurring before adult life there are reported, according to Birch-Hirschfeld,[3] only four recoveries, and even these are not without question as to either the correctness of the diagnosis or the permanency of the cure. It seems at least certain that recovery is possible only in the early stages of the disorder. The progress of leukæmia is usually slow, and the affection lasts several years. In children the course is generally much shorter, and in proportion to the youth of the patient; and in some cases it has terminated within a few months. Golitzinsky[4] claims to have seen death occur in an infant after the disease had lasted but three weeks, and Eichhorst[5] reports the death of a boy after twenty-four days of illness. Epstein[1] even describes a distinct form—acute leukæmia—which lasts never more than nine weeks. It may begin quite suddenly, after a short prodromal stage of variable nature, consisting of intense headache, or slight fever, or respiratory symptoms, etc. In other cases it is preceded by severe anæmia.

[4] Jahrb. d. Kinderheilk., 1861, iv. 90.

[5] Spec. Path. u. Therap., 1885, iv. 10.

The prognosis as to the duration in each individual case depends further on the rate with which the hyperplasia of the lymphadenomatous tissue advances, and on the percentage of leucocytes in the blood; though Fagge[2] attributes more importance to the degree of diminution of the number of red blood-cells, and to the intensity of the dyspnœa. Death generally takes place as the result of increasing exhaustion, and with hydræmic symptoms due to great anæmia. Hemorrhage from the nose, mouth, lungs, kidneys, bowels, or other parts, or into the brain, is often the immediate cause of death. Diarrhœa, too, may bring on the fatal termination, and pneumonia is a not infrequent cause of it in childhood, while other complications may in some cases be at fault.

Treatment.—The treatment of leukæmia is most unsatisfactory. Quinine and iron should be tried, given in large doses and for a long period, as good results have been claimed for them when administered in the early stages. Mosler[3] reports recovery in a boy of ten years under the use of this treatment; and this case is probably one of the most certain of the reported instances of recovery in children. He further[4] recommends piperin and oil of eucalyptus, on the ground that they produce contraction of the spleen. Arsenic in large doses should also be tried, as it has been claimed that success has been obtained with it. Injections of arsenic into the body of the spleen have also been recommended. Goodhart[5] reports improvement in six cases of possible leukæmia in children under the employment of cod-liver oil, phosphorus, or iodide of iron. Ergot internally or by injection, and the local employment of mercury, cold, and electricity, may be used, but little is to be expected from them. If there be any suspicion that congenital syphilis is the cause of the disease in a given case, a course of mercurial treatment should be instituted; though it is often valueless, and may even do harm. Transfusion of blood has been employed without much benefit. The ill results of extirpation of the spleen are seen in the twenty cases collected by S. W. Gross,[6] only one of which recovered, and in this the disease was in the incipient stages. The inhalation of large quantities of oxygen is a means of treatment which has recently come into prominence. Kirnberger[7] reports a case in a boy of ten and one-half years cured in this way. In other cases[8] marked temporary improvement has been obtained with it. Da Costa and Hershey[1] report two cases greatly improved by it; one of them being in a boy of thirteen years. Others, however,[2] have not succeeded in benefiting patients with oxygen. The diet and hygiene must, of course, be carefully attended to. Diarrhœa, vomiting, hemorrhage, and other disturbances call for treatment appropriate to them. The chief point to be borne in mind in this connection is the necessity of strict watch over, and perhaps of energetic treatment of, any case of chronic enlargement of the spleen or lymphatic glands in a child, lest it prove to be the prodromal stage of a leukæmia or other serious cytogenic disorder.

SIMPLE CONSTITUTIONAL ANÆMIA.

Definition.—This condition may be defined as a cytogenic, non-leucocytic anæmia of moderate degree, due to some primary derangement of the blood-making organs without discoverable anatomical basis.

Pathology.—It has been questioned whether such an affection exists; and it is certain that many cases which might at first sight be assigned to this category will on more careful study be found to be symptomatic of some other disorder. Yet children after the first few days of life begin to be physiologically anæmic; and it is probable that many cases of anæmia in them merely exhibit a pathological exaggeration of this physiological disposition. An anæmia of this variety may even be congenital, occurring most frequently in the case of children who are born undersized and poorly developed, yet without the existence of any actual constitutional malady. Such are the children born often prematurely, or of delicate parents who yet have no discoverable disease. Henry[3] reports an interesting instance of congenital anæmia of this sort; the parents being immature, and the child weighing but six and three-fourths pounds and having only 3,625,000 red blood-cells to the cubic millimetre. The ratio of red to white cells equalled 1:145. In cases of constitutional anæmia there would seem to be "a congenital deficiency in the composition of the blood;"[4] "a congenital disproportion between the functionally active elements of the blood and the tissues of the body to be supplied by them."[5] There perhaps exists in these cases an inborn inactivity of the hæmatopoietic system, producing a blood characteristic of anæmia. Treatment may remove the anæmic condition, or it may persist throughout the whole or a great part of the life of the individual. Again, though the child may not be anæmic at birth, there may be an inborn tendency to become so as growth advances, this being due in some instances to an inability on the part of the blood-making organs to keep pace with the increase in the size of the body. A marked analogy is thus evident between the pathology of this affection and that of chlorosis.

[4] Henry, Anæmia, 1887, p. 20.

[5] Immermann, Ziemssen's Handbuch d. Spec. Path. u. Therap., 1875, xiii. 1, 280.

Strümpell[1] believes that Virchow's explanation of the cause of chlorosis possibly applies to many cases of congenital anæmia, and Jacobi[2] says that he has seen a number of such cases in which the supply of blood to the body was diminished by the anomalous smallness of the heart and vessels. Strictly speaking, these cases cannot be included in this category, since they are really secondary to the anatomical condition, and have nothing to do with a functional inefficiency of the blood-making apparatus.

The **symptoms** of this type of anæmia do not differ from those usually found in the secondary forms already described.

The **diagnosis** rests on the early development of the anæmia secondary to no discoverable disease.

The **prognosis** tends to be unfavorable, since the cause is often a firmly-seated, constitutional one.

Treatment is similar to that recommended for the non-cytogenic varieties.

SPLENIC ANÆMIA.

Synonymes.—Splenic anæmia, Anæmia splenica, Splenic cachexia, Splenic pseudo-leukæmia.

Definition.—Splenic anæmia is a cytogenic anæmia of pronounced degree depending on a decided enlargement of the spleen, and characterized by a marked diminution in the number of the red blood-cells without noteworthy increase in the number of leucocytes.

Although isolated cases of this nature have frequently been described, the disease has received little or no attention at the hands of most writers. It has, however, been discussed by Strümpell,[3] Henry,[4] and Banti,[5] among others.

Etiology.—The enlargement of the spleen appears to be the principal factor in producing the anæmia, but the cause of this enlargement cannot be discovered in all cases. Hypertrophy of the spleen is a constant attendant on profound malarial cachexia, and is also a prominent feature in hereditary syphilis. Barlowe and Bury[6] say that it is usually absent in rickets even when severe, and that, when present, it and the accompanying anæmia are not characteristic of rickets, but belong to a separate cachexia.

[6] This Encyclopædia, ii. 231.

Although the anæmia attending these forms of splenic enlargement is often classified as symptomatic of the primary affections, yet it is too profound to be considered merely the result of the general effects of these upon the constitution. The blood-disorder owes its existence rather to the splenic affection itself,—*i.e.*, it is a splenic anæmia, and belongs to the cytogenic forms. This is shown by the fact that the anæmia does not develop to an intense degree in these diseases unless, and until, the spleen hypertrophies.

Splenic anæmia may occur in children of all ages as well as in adults. Eustace Smith[1] reports two interesting cases occurring in boys of twelve and nineteen months respectively, and, as early as 1856, Friedrich[2] published a carefully-studied case in a boy of five and three-fourths years. Smith considers the condition not infrequent in infancy and early childhood, and expresses the view that most instances of extreme anæmia in young children are of this nature.

Symptoms.—The symptoms begin insidiously with a progressive enlargement of the spleen, which often attains a great size. Anæmia develops simultaneously, and increases, producing at first symptoms similar to those of the non-cytogenic forms, which, however, later become extreme unless the disease is arrested. The tint of the face is characteristic, being in severe cases that of ivory or of yellow wax, with a faint olive color and a decided transparency.[2] Œdema and serous effusions are common in advanced cases, petechiæ and ecchymoses are also witnessed, and epistaxis is frequent. Emaciation may or may not be present, and is rarely extreme. Muscular prostration is intense. The bowels are easily affected, and the appetite in older children is diminished or perverted. Mental hebetude may be witnessed. There is often slight irregular pyrexia. The urine does not contain albumen.[3] The red blood-cells are greatly diminished in number, and resemble in appearance those seen in pernicious anæmia. Strümpell describes nucleated red blood-cells in blood from the pulmonary, hepatic, and splenic veins, though Banti says that they have never been seen in this affection. The white blood-cells are increased in number to some extent in certain cases, and not affected in others.

Pathological Anatomy.—Post-mortem lesions appear to be most marked in the spleen. This organ is much enlarged and hard, and is usually described[4] as of a deep-red color on section. Under the microscope the normal adenoid tissue is found to have largely disappeared, while the fibrous tissue has greatly increased in amount. There exist atrophy and sclerosis of the Malpighian bodies.[5] Fatty changes are visible in the heart and voluntary muscles. The marrow of the long bones may present in some cases the same dark-red lymphoid appearance frequently seen in pernicious anæmia.[1]

[4] Wood, American Journal of the Medical Sciences, October, 1871; Ashby and Wright, Diseases of Children, 1889, p. 309.

[5] Banti, loc. cit.

Pathology.—Splenic anæmia is sometimes described as the splenic form of Hodgkin's disease, and this is the opinion adopted by Banti. Others believe, with good reason, that it is entirely distinct from it. The distinction is based largely on the anatomical differences in the appearance of the spleen in the two affections. In splenic anæmia the appearance is as here described, while in Hodgkin's disease the characteristic change, and the one usually seen, is an hypertrophy of the Malpighian bodies, giving a variegated aspect to the section of the organ. Clinically, too, the affections are to be distinguished. I can recall two well-marked cases of splenic anæmia, seen within the last three years, occurring in a woman and a girl respectively, which seemed to bear but little resemblance to lymphatic anæmia either in symptoms or in course.

In the present state of our knowledge it is probably best to designate as splenic anæmia all those cases in which the anæmia appears to depend on enlargement of the spleen, whatever the cause of the hypertrophy may be, and in which there is no involvement of the lymphatic glands or leukæmic alteration of the blood.

Diagnosis.—The diagnosis rests upon the combination of extreme non-leucocytic anæmia with marked and uniform splenic enlargement without involvement of the lymphatic glands. Tumors of the spleen do not produce the symmetrical enlargement characteristic of the anæmic affection. Leukæmia is to be distinguished by the different character of the blood, Hodgkin's disease by the predominating involvement of the lymphatic glands, and pernicious anæmia by the absence of marked splenic enlargement.

Prognosis.—Ashby and Wright[2] say that most of the cases in children recover, and Eustace Smith,[3] though more guarded, does not give an unfavorable prognosis in all cases. It is probable, however, that permanent cures of splenic anæmia are of the rarest occurrence,[4] unless the splenic enlargement be due to syphilis or malaria. The disease is very apt to intermit, with periods of health lasting several months, during which time the splenic enlargement diminishes. The total duration of the disorder is from five or six months to three years.[5] Death in children is usually due to a severe attack of diarrhœa, or to the development of bronchitis or pneumonia.

Treatment.—The same internal constitutional treatment should be employed as has been recommended for the severe forms of non-cytogenic anæmia, and, besides this, especially unfavorable symptoms must be treated as they arise. Particular care should be given in the case of children to the removal of gastro-intestinal irritation. All chilling of the body should also be guarded against by warm clothing. Fresh air is of great importance. In older children injections of arsenic into the spleen and faradization over the splenic region may be employed. Mercurial inunctions in this locality may do more harm than good, unless there is positive evidence of the existence of syphilis.

LYMPHATIC ANÆMIA.

Synonymes.—Hodgkin's disease, Pseudo-leukæmia, Anæmia lymphatica, Adénie, Malignant lymphoma, Lymphadenoma, Lympho-sarcoma, Adenoid disease, Lymphatic cachexia, Desmoid carcinoma, Diathèse lymphogène, etc.

Definition.—A progressive non-leucocytic anæmia, depending on a wide-spread overgrowth of the lymphatic glands and sometimes of the spleen and other lymphatic tissues, together with the secondary development of heteroplastic lymphatic growths in various tissues of the body.

History.—The affection was first clearly described by Hodgkin in 1832,[1] though fatal cases of enlargement of the lymphatic glands had been previously reported by Morgagni and others. Cases occurring in children were among the first reported by Hodgkin, though, as no examination of the blood was made in any of them, it is possible that some may have been instances of leukæmia. Wilks in 1856[2] directed renewed attention to the disease, and since this time the instances of the affection both in adults and in children have been numerous.

Etiology.—The causes of lymphatic anæmia are unknown. In certain instances some such constitutional disorder as syphilis or phthisis has existed in the parents; in others the disease has followed rickets or intestinal catarrh or some acute disease, and has possibly been induced by it. Trousseau[3] believed that local irritations, such as otorrhœa, carious teeth, eczema, chronic pharyngitis or rhinitis, and the like, may at times exert an influence in starting the affection in the cervical glands.

Age is an important predisposing cause; a large proportion of those affected being children or young adults. Of the 100 cases tabulated by Gowers,[4] 30 were under twenty years of age, and 16 of these under ten years. Eustace Smith[5] reports an undoubted case in an infant of eight months, who had first exhibited the disease at three and one-half months of age; and states that the usual age at which children are attacked is from four to five years and upward.

[4] Reynolds's System of Medicine, 1879, v. 306.

[5] Diseases in Children, 1884, 220.

Sex also appears to be an important factor, more boys than girls being affected: 75 of Gowers's 100 cases, and 40 of Hutchinson's[1] 58, were males.

Symptoms.—The symptoms may be divided into the regular or constitutional, and the accidental or secondary, these latter resulting from the pressure of the enlarged glands in different parts of the body. The disease further exhibits two periods or stages. Though it may in rare instances begin with a lymphomatous degeneration of the tonsils, yet the earliest symptom usually observed is a painless enlargement of the lymphatic glands, seen first, as a rule, in the neck. The swelling generally appears on one side first, and then spreads under the chin to the other side. This condition may remain unaltered for months or even for years, and during this first period of the disease there may be no constitutional symptoms of any moment, and the tumors remain isolated, painless on pressure, and movable under the skin. Sooner or later, however, the second period of the disease develops. The glands of the neck now rapidly increase in size and coalesce into large masses, and in most cases those of the axilla are also attacked, and less frequently those of the groin. The advancement of the disease to other parts of the body is attended or closely followed by a high grade of anæmia, emaciation, and prostration of strength. Some enlargement of the spleen may be detected at this stage, but great overgrowth is rather an unusual feature; though I have seen the organ in one instance, in a male adult, present a percussion-dulness extending downward from the nipple to the crest of the ilium, and horizontally from within an inch of the umbilicus to the normal dulness of the spinal region. An hypertrophy such as this is, however, very uncommon. Less frequently the more deeply situated glands of the body are involved, and may form huge masses in the abdomen and mediastinum. Sometimes, indeed, these glands may be the first to be attacked. The greater the degree of glandular involvement, the greater does the cachexia become.

Variations from the usual course of the disease may be witnessed. For example, the enlargement of the spleen may occasionally be discovered before that of the lymphatic glands,[2] though this is probably very exceptional. In other instances the deeper groups of glands may be first attacked, and the various pressure-symptoms may at first involve the true nature of the case in great obscurity. Sometimes, too, the anæmia and other constitutional symptoms develop before any local evidence of the affection can be found. In other cases, even when the glandular involvement is advanced, there may never be decided anæmia.

Fever is one of the most frequent symptoms. In the early stages it is slight; but when the disease is well under way it may be of an irregular, intermittent, hectic type, or continuous and high. Sometimes attacks of high fever are witnessed, lasting several days and accompanied by increased swelling of the glands.

---

[1] Transactions of the College of Physicians of Philadelphia, 1875, viii.

[2] Eichhorst, Spec. Path. u. Therap., 1885, iv. 17.

Various other symptoms may be noted, some due to the anæmia, many to the enlargement of the glands or to the deposition of lymphatic tissue in various parts of the body. Among them are shortness of breath on exertion; palpitation of the heart; hoarseness from pressure on the pneumogastric or recurrent laryngeal nerve; more or less cough from pulmonary involvement, or from tracheal or bronchial stenosis; pleural or abdominal effusion from pressure on the veins, or from irritation of the serous membranes by lymphatic growths; diarrhœa or obstinate constipation; indigestion and vomiting; difficulty in swallowing; localized œdema from profound anæmia or from pressure; icterus from the growth of lymphatic tissue in the liver. Headache and dizziness may result from the anæmia, and neuralgias of various parts of the body may appear. There may be great apathy, dulness of mind, and indisposition on the part of the child to talk. Paralysis from pressure may be witnessed, as in the child of six years reported by Goodhart[1] and in a case of Hutchinson's.[2] Epistaxis is not as common as in leukæmia. Itching of the skin is frequent in advanced cases, and ulceration and hemorrhagic spots of various sizes may be present. Bronzing of the skin has been noted,[3] papular rashes may exist, and Wagner[4] has reported three cases of prurigo in lymphatic anæmia. It is a notable fact that the size of the enlarged glands may vary greatly from time to time in some patients.

The urine is usually not altered, but may occasionally contain albumen. In a child ten months old reported by Goodhart[5] the urine towards the end of the disease was red with blood.

The condition of the blood varies considerably in different patients. In the early stages it is usually entirely unaltered, and even after the glands in various parts of the body are affected the normal condition may persist. I have quite recently had under my care a patient in whom the submaxillary and parotid lymphatic glands on both sides were decidedly enlarged and were adherent to each other to some extent, while some of the superficial cervical and axillary glands were also involved. The blood, however, gave a hæmoglobin percentage of 90, and the red blood-cells numbered 5,920,000 to the cubic millimetre. Still, in general, as the disease advances the blood exhibits the characteristic lesions of an anæmia more or less severe. It is thin, pale, and watery, and coagulates slowly. The number of red blood-cells is often much reduced, but never as greatly as in many cases of pernicious anæmia. In a very severe case of lymphatic anæmia, with excessive hyperplasia of the lymphatic tissue, I still found 2,944,000 corpuscles to the cubic millimetre. Rarely there may be no reduction, even in advanced cases.

The white blood-cells are usually little if at all increased in number. Sometimes, however, they are greatly in excess, so that the disease actually approaches leukæmia and may even be apparently transformed into it. Poikilocytosis may be present to some degree. Microcytes are often abundant. Osler[1] has never found nucleated red blood-cells, and says that the number of blood-plaques is variable.

Pathological Anatomy.—In the early stages of the disease the lymphatic tumors are isolated and free from the skin, and exhibit simply an overgrowth of the glandular tissue, the natural appearance of the gland and the continuity of the capsule being preserved. In the later stages the glands may coalesce and form very large, irregularly-shaped masses, the lymphoid growth rupturing the capsule, and sometimes even spreading by continuity into the adjacent tissues, and perhaps, if superficial, ulcerating through the skin. There may also be true heteroplastic growths of adenoid tissue in different organs of the body.

The lymphomata, including the metastatic growths, are identical in nature with those seen in leukæmia. They may be of either the hard or the soft variety, according as the hyperplasia of the reticulum or that of the cells predominates. In the soft variety, which is much the more common, the glands may be even in an almost fluctuating condition. There is no sharp line of demarcation between the two forms, and a gland at one time soft may become hard, or the reverse may sometimes occur. On section the hard lymphomata are of a grayish-white, fibroid appearance, while the soft glands are of a grayish-red, marrow-like quality, and give a creamy juice when scraped. Under the microscope the soft form exhibits numerous cells like lymph-corpuscles, together with some giant-cells, but the reticulum can scarcely be seen. In the hard form the development of the reticulum varies proportionately to the hardness of the gland. The tumors may sometimes undergo an amyloid degeneration ; more often they take on a fibroid induration, very seldom suppurate, and become caseous extremely rarely.

The superficial glands are those most generally involved, the cervical being oftenest attacked, and those of the axilla next. Of the internal glands those of the thorax are oftenest diseased. The retro-peritoneal glands are those in the abdomen most frequently hypertrophied.

Evidences of encroachment on different organs and of pressure in the most diverse localities may be found on post-mortem examination.

According to Gowers,[2] the spleen is hypertrophied or exhibits new growths of lymphatic tissue in about 75 per cent. of all cases, but the enlargement is generally not great. It is due either to a simple hyperplasia of the pulp, or more commonly to an extreme development of lymphatic tumors in the organ. These tumors are merely one or several united, greatly-hypertrophied Malpighian bodies. They vary in size from that of a pin's head to that of a walnut, and are of a white or yellowish color, in strong and characteristic contrast to the dark-red color of the splenic tissue. They are round or irregularly shaped, and may be one or two or very many in number. Histologically they are of the same structure as the hypertrophied lymph-glands. Resembling somewhat tubercular masses, they may be readily distinguished by the absence of any caseation, as well as, according to Langhans,[1] by the relative position of the reticulum and the cells in the two diseases; the cells occupying the centre of the nodule in the lymphoma, the connective tissue the centre in the tuberculous mass.

[1] System of Medicine by American Authors, 1885, iii. 924.

[2] Reynolds's System of Medicine, 1879, v.

The marrow of the long bones has in a very few instances in adults been found red and lymphoid, as in the case reported by Ponfick.[2] Such a change has, I believe, not yet been found in children. In quite young children the marrow of all the bones is, of course, normally of this nature.

The thymus and thyroid glands, the suprarenal bodies, and the parotid glands have been reported involved. The tonsils and pharyngeal tonsil, and the follicles at the base of the tongue, are in some cases enormously hypertrophied. Lymphoid growths are sometimes seen in the stomach, and the small intestine may be similarly and very extensively affected and its walls much thickened. Ulceration of Peyer's glands may be the cause of diarrhœa. The large intestine also may be much involved. The liver is often enlarged and contains scattered small white lymphoid growths beneath the capsule or in the interlobular connective tissue; or there may be an interacinous lymphoid infiltration of the nature of an incipient cirrhosis. The pancreas at times contains lymphoid growths. The kidneys are enlarged in many cases, and exhibit a diffuse interstitial lymphatic growth, or a formation of distinct nodular masses. The testicles and ovaries, brain and spinal cord, are occasionally attacked. Lymphatic nodules frequently occur in the lungs, and resemble tubercular masses in appearance. They are found in greatest number about the bronchi. The heart may occasionally contain secondary lymphoid growths. It very often exhibits fatty change if the anæmia has been severe.

Pathology.—The pathological basis of the disease is a tendency to an overgrowth of lymphatic tissue throughout the body. This is almost invariably primary in the lymphatic glands, while the spleen is affected secondarily and to a much less degree, and the medulla of the bones but rarely. The tendency to generalization in many glands, together with the disposition to metastatic growths, renders it possible that the disease is of an infectious nature, and this view has been adopted to some extent. According to Wunderlich[1] and others, the spleen may be primarily diseased, with secondary involvement of the glands. A classification has been made by some writers in which splenic, lymphatic, and medullary forms of the affection have been described, as in leukæmia; but the idea of pure splenic and medullary forms conflicts with the definition and the essential characteristic of the disease,—namely, an hypertrophy of the lymphatic glands. The first may be with much greater propriety referred to "splenic anæmia." As to the second, it seems very possible that such a change in the bone-marrow is to be regarded as secondary to the anæmia, rather than as a cause of it; and in any case the nature and symptoms of this form of the disease could scarcely be distinguished from, if they be not, indeed, identical with, those of pernicious anæmia. (See Pernicious Anæmia.)

---

[1] Virchow's Archiv, liv. 525.

[2] Ibid., lvi. 550.

The relation of lymphatic anæmia to leukæmia is a very close one, and the lymphoid overgrowth does not essentially differ in the two affections. In leukæmia, however, the spleen and medulla of the bones are much more liable to be affected than are the lymphatic glands, and it is exceptional that the internal glands are much enlarged. The gross and microscopic appearances of the spleen in the two diseases are usually not alike; lymphomata in the organ being unusual in leukæmia, but very common in lymphatic anæmia. The difference in the character of the blood constitutes, nevertheless, the principal anatomical distinction between the two, and even this is not constant, since cases of transition from one to the other disease have been reported more than once. (See introductory remarks on Classification of anæmias.) The question has been raised whether any actual pathological difference exists.[2] It has been suggested[3] that the rapid growth of the lymphatic tissue in lymphatic anæmia did not allow time for the development of the leukæmic change in the blood; but this would not explain those cases in which the hyperplasia had always gone on slowly, yet no increase in the number of white blood-cells appeared. Fagge[4] takes the ground that the leukæmic condition of the blood is only an accidental circumstance complicating the overgrowth of lymphatic tissue. The remark of Birch-Hirschfeld[5] expresses accurately the state of the case,—viz., "that as long as we know as little of the etiology of malignant lymphoma as we do of that of leukæmia, the question as to the identity of or the difference between the two cannot be definitely determined."

Complications and Sequelæ.—A scorbutic stomatitis has been witnessed as a complication of lymphatic anæmia. Diphtheria and dysentery have also occurred. Pleuritic effusion and œdema of the lungs are not uncommon, tuberculosis may develop, and catarrhal pneumonia is one of the most frequent and fatal complications in children. Various affections of the skin, including bed-sores and furuncles, may arise, and erysipelas has been observed. Convulsions or coma may appear in the later stages.

[4] Practice of Medicine, 1886, ii. 352.

[5] Pathological Anatomy, 1883, ii. 131.

Diagnosis.—The diagnosis, though usually easy, may at times present great difficulties, especially in the early stages of the disease. Lymphatic anæmia is to be distinguished in the first place from leukæmia, and this is to be accomplished mainly by the study of the blood, while, apart from this, leukæmia is much more apt to be attended by greatly-enlarged spleen, hemorrhages, and diarrhœa, and seldom exhibits the enormous glandular hypertrophy of the other affection. Lymphatic anæmia is further to be distinguished from local benign lymphomata and from lympho-sarcomata. The first of these is a simple but persistent hypertrophy of certain glands, and is of an entirely benign nature, without disposition to extend to other parts. The second is not uncommon in children, and may present difficulties in recognition. It is a localized, small-celled sarcoma of the lymph-glands, spreading by contiguity to the surrounding tissues, and undergoing metastases. The structures involved in the spread of the disease are organs rather than glands. There is not, in fact, the general involvement of one group of glands after the other, and of the lymphadenoid tissue throughout the body, as is the case in lymphatic anæmia. The affected gland is, moreover, sarcoma, and is usually adherent to the skin.

Scrofulous enlargement of the cervical glands is the condition most liable in children to be confounded with Hodgkin's disease, and in some cases cannot be distinguished from the early stages of the latter. Even later in the disease the diagnosis may be difficult, as scrofulous glands sometimes form masses as large as in advanced lymphatic anæmia. Yet other evidences of the scrofulous affection can usually be discovered, or there is a distinct family taint. The glands in scrofula are harder and less elastic, seldom so numerous, more often submaxillary than in the anterior and posterior triangles as in Hodgkin's disease, often early become adherent to each other and to the skin, and exhibit a decided disposition to suppurate.

Prognosis; Course; Duration.—The prognosis of lymphatic anæmia is almost uniformly unfavorable. There occurs a more or less rapid consecutive involvement of different groups of glands, with an advancing cachexia which sooner or later terminates in death from asthenia, unless the patient is carried off by some complication, as by catarrhal pneumonia, or by conditions arising through the pressure of the enlarged glands.

The duration of the disease varies from a few months to four or five years, depending largely on the rapidity with which the lymphoid hypertrophy advances and upon the position of the enlarged masses. Guitéras[1] reports the case of a child of five years, in whom the disease lasted but one month from the first enlargement of the cervical glands until death supervened. There may be periods during which the disease ceases to advance and the tumors to increase in size. A few cases of recovery have been reported; as, for example, by Seitz[1] in an eight-year old boy. Henry[2] does not consider the prognosis so unfavorable as is usually supposed, particularly if the disease be recognized sufficiently early to permit of operative interference.

---

[1] Ann. Univ. Med. Sci., 1888, i. 416.

Treatment.—The most favorable hygienic conditions should be sought for the child as early as possible in the case. Cod-liver oil, iron, and quinine may be employed as general tonic measures, but are without specific action in arresting the growth of the glands. Iodine has been applied externally and injected into the tumors, and has also been given internally; and mercurial inunctions have been employed. Seitz's case recovered under the administration of iodide of potassium, digitalis, and finally of iron. Phosphorus has been advocated, and frictions and electricity locally applied have been claimed to be useful. Generally, however, all treatment is without avail, though there would appear to be more testimony to the value of arsenic than to that of any other drug. Its administration should be commenced early, and it should be given persistently and in as large doses as the child will bear. If the tumors be of small size and confined to one region, and have not been benefited by appropriate treatment, and if the general condition of the patient be good, the removal of the glands by operation is to be strongly recommended as offering the best chance for permanent cure. The earlier this operation is performed the better. Gowers[3] recommends that it be not performed on patients in whom the number of red blood-cells is below 60 per cent. of the normal. In case treatment directed against the disease is of no avail, a purely symptomatic method of procedure must be adopted. Tracheotomy or other surgical interference will sometimes be demanded for the relief of pressure-symptoms.

PERNICIOUS ANÆMIA.

Synonymes.—Progressive pernicious anæmia, Idiopathic anæmia, Essential pernicious anæmia, Anæmatosis, Essential malignant anæmia, Essential febrile anæmia.

Definition.—An extreme and increasing anæmia without loss of flesh, not secondary to any discoverable adequate cause, and nearly always terminating in death.

History.—Though isolated instances were previously reported by Andral,[4] Coombe,[5] Hall,[6] Piorry,[7] and others, the first to describe a series of cases was Channing in 1842.[1] In 1855, Addison[2] gave a clear account of the affection, under the title of "Idiopathic Anæmia." Renewed interest was awakened in the subject by the writings of Gusserow[3] and of Biermer[4] in 1871 and 1872. Taylor[5] collected 23 cases which had been reported by various observers up to 1878. Since this time the number of published instances of the disease has greatly increased, and important contributions regarding it have appeared from the pens of Eichhorst,[6] Quincke,[7] Immermann,[8] Müller,[9] Lepine,[10] Osler,[11] Pye-Smith,[12] Pepper,[13] Mackenzie,[14] Musser,[15] and many others; including the valuable contributions to the pathology of the affection recently made by Hunter.[16] As the first instance in which the disease was seen in childhood may be designated one of the cases reported by Addison,[17] in a boy of sixteen years; or the still younger patient, a girl of eleven years, whose case is recorded by Leared.[18]

Etiology.—Locality has possibly some influence in the production of pernicious anæmia; the disease seeming to be more common in Switzerland and Northern Germany than in Southern Germany, Austria, England, France, and America; while in Italy, Russia, and the Spanish Peninsula it is rare.[19] Though not common in adults, it is still less often seen in children. Most cases appear between twenty and fifty years of age. The youngest case on record is said to have occurred in a girl of sixteen months.[20] Elben[21] reports it in a girl of three years, and Kjellberg[22] in a boy of five years. Other instances of its occurrence in persons under twenty years of age have been recorded by Quincke[23] (girl of eleven), Habershon[24] (girl, fifteen), Kahler[1] (boy, twelve), Cayley[2] (boy, seven), Mackenzie[3] (boy, ten), Huguenin[4] (girl, eight), Gull[5] (boy, age not given), Biermer[3] (girl, eighteen), Haven[6] (girl, ten), and Bradford[7] (girl, eleven).

Of 102 cases collected by Pye-Smith only 6 were less than fifteen years of age, and 4 were between fifteen and twenty.

Statistics indicate that females are more predisposed to the disease than males. In this estimation are included the cases developing after parturition. If these be omitted, as parturition is itself a predisposing cause, the influence of sex appears to be immaterial. The number of cases which have occurred in children is too small to allow of conclusions being drawn; though rather more female than male children have suffered from the disease.

A lack of proper hygienic conditions and insufficient nourishment may possibly have a slight predisposing influence, yet this appears by no means certain. Pregnancy and parturition, common predisposing causes in adults, of course need not be considered in this connection. Bodily over-exertion or exposure, the previous occurrence of some acute disease, anæmias of other forms, gastric and intestinal disturbances, mental or nervous shock, etc., have in different cases immediately preceded and perhaps predisposed to the affection; in the case of Gull referred to, the boy had been greatly frightened by being attacked by sheep in a field. Where there has been profuse hemorrhage or diarrhœa preceding the anæmia, it is questionable whether this can be classed as pernicious anæmia, but is not rather to be considered a secondary form. Yet if the condition of the blood grows steadily worse after the apparent cause has been removed, the preceding anæmia can be looked upon as a predisposing cause of pernicious anæmia. It is always to be borne in mind in considering the etiology of pernicious anæmia that the essential feature of this affection is its origin without adequate discoverable cause apart from some as yet unknown alteration of the blood-making apparatus or direct destruction of the blood itself.

Klebs[8] reported the occurrence of species of *Cercomonas* in the blood, and Frankenhäuser[9] that of micrococci, but it is uncertain whether these possess any etiological relation to the affection. Kjellberg[10] believes that the disease is probably an infectious one, and the possibility of this being the case is strengthened by the fact that it appears epidemically to a certain degree in Switzerland. Very many cases do not offer even a predisposing factor in explanation of their development.

Symptoms.—Pernicious anæmia usually comes on so insidiously that the date of onset can scarcely be determined. At first there simply appear increasing pallor, weakness, shortness of breath, and other evidences of anæmia. When the disease is well established, the color of the skin is often a striking one, being not ashen, but of a pale-lemon tint, simulating jaundice. The conjunctivæ may have a similar hue. This peculiar shade of the skin has been repeatedly referred to by authors, and is very characteristic when well marked. The subcutaneous fat is very rarely diminished, and is not uncommonly increased in amount. Slight œdema of the extremities and face may occur, and petechiæ may develop. The mucous membranes are very pale, the tongue is swollen and dry, and the bones are sometimes tender on pressure.

The pulse is often peculiarly full, but very compressible. Palpitation of the heart comes on with the slightest exertion. Anæmic murmurs of various sorts are often heard over the heart,—sometimes so loud that they simulate organic murmurs, especially as they may be accompanied by a distinct thrill. The cardiac dulness, however, indicates a heart of normal size or but slightly dilated, unless hydro-pericardium has developed. A systolic murmur may be heard in the arteries, and a loud venous hum in the jugulars.

Dyspnœa is often very great on the slightest exertion, and is sometimes persistent. Hydrothorax may come on near the end of life. Ringing in the ears and dizziness are evidences of the anæmia, and debility may be so great that the patient is confined to bed, and cannot sit upright on account of the symptoms of cerebral anæmia which this movement produces. The development of the hemorrhagic diathesis is a frequent symptom of the disease. Epistaxis is very common, and is sometimes among the earliest symptoms; and hemorrhages from the bowels or the gums may exceptionally occur. Retinal hemorrhages are present in the majority of cases, and may impair vision.

The appetite is usually lost, and an atonic state of the digestion, with diarrhœa, nausea, and vomiting, is very frequent. In most cases there is fever of an irregular type, usually with an evening rise of from 2° to 4° F. or even more. Sudden falls of temperature during the twenty-four hours are sometimes seen. A peculiarity of the temperature consists in the occurrence of periods of apyrexia lasting several days or weeks. Towards the close of life there is a tendency to fatal collapse, with great depression of temperature.

The urine is of low specific gravity, and generally contains more uric acid than normal. Statements regarding the excretion of urea vary. Albuminuria is rarely seen. In a case recently reported by Hunter[1] the urine was of a deep sherry-color, and contained a large amount of pathological urobilin. He considers that this substance, renal epithelium, and perhaps a few casts containing blood-pigment, together with an increased excretion of iron, are features of the urine which, when present, are characteristic of pernicious anæmia. This same dark color of the urine was remarked repeatedly in a patient under the care of Pye-Smith;[1] and Henry,[2] Mott,[3] and others have also noticed it. Mott[4] has recently reported a second case, in which the same dark color was observed, and an excess of urobilin determined with the spectroscope.

---

[1] Practitioner, September, November, December, 1889.

There may be no symptoms pointing to the brain, except that answers to questions are often given only after a long pause, as though thinking were done slowly. Either sleeplessness or an unnatural tendency to sleep may be present. Delirium is occasionally witnessed.

Lichtheim[5] has reported three cases in which the symptoms of tabes accompanied those of pernicious anæmia, and believes that the combination is of common occurrence. Lepine, too,[6] has seen wide-spread atrophic paralysis develop in pernicious anæmia. I have recently seen a case of the disease in the practice of Dr. W. H. H. Githens, of Philadelphia, in which evident nervous symptoms were present, consisting in tingling and a subjective sense of coldness in the extremities, especially the legs and feet, and diminution of the power of walking, apparently not due to loss of strength.

The ratio of the weight of the blood to the total weight of the body has been calculated to be much diminished in pernicious anæmia, and its specific gravity also less (1028.2, Quincke). When drawn from the finger it appears strikingly pale and watery, and often scarcely enough can be expressed to permit of accurate examination. It coagulates very slowly. The amount of fibrin is diminished. The number of red blood-corpuscles is very greatly reduced, often more than in any other form of anæmia. A count of 1,500,000 or 1,000,000 represents an average case, while a reduction to even 500,000 has been repeatedly though less frequently witnessed. In a case reported by Quincke[7] the number of red cells equalled 143,000 per cubic millimetre. Macrocytes are generally stated to be numerous; while a photograph published by Henry[8] and here reproduced indicates that a majority of the red blood-corpuscles may be greatly increased in size. Eichhorst,[9] too, states that the average size of the red blood-cells in pernicious anæmia equals 8.9 instead of 7.6 micro-millimetres as in normal blood. Microcytes are nearly always present, and the small, round, and deeply-colored forms have been described[10] as very commonly seen, though some observers have not always found them.[11]

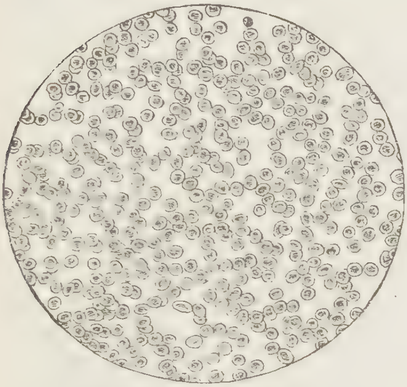
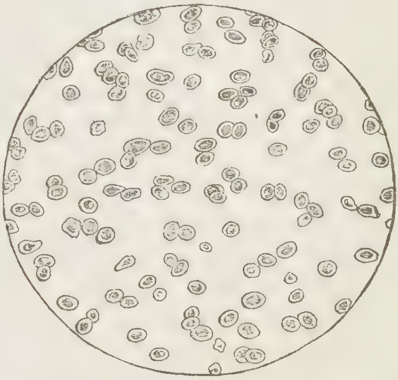
Poikilocytosis of very marked degree is seen to greater advantage in pernicious anæmia than in any other condition. The red blood-cells lie singly or in poorly-formed rouleaux. Nucleated red cells have been only occasionally described, though Ehrlich[1] claims that they are nearly always present in all forms of severe anæmia; and Neumann[2] also has found them in severe post-hemorrhagic cases. The hæmatoblasts are absent or very few in number.[3]

FIG. 9.



Photograph of normal blood.

FIG. 10.



Photograph of blood in pernicious anæmia.

The ratio of the number of leucocytes to that of the red cells may be normal or diminished, or sometimes decidedly increased. It has been noticed that the hæmoglobin readily crystallizes out of the red blood-corpuscles in this disease.[4]

A very important characteristic, to which attention has repeatedly been called by writers, is the relatively high percentage of hæmoglobin present. In other forms of anæmia the percentage of hæmoglobin is generally much smaller than that of the red blood-cells, but in pernicious anæmia it nearly equals or very commonly exceeds it to some extent, so that the hæmoglobin value of each corpuscle is actually greater than normal. Laache[5] views it as almost pathognomonic of pernicious anæmia, and Hunter[6] says that this condition of the hæmoglobin is the only strictly characteristic feature of the blood in this disease, as all the others referred to may be present to some extent in other conditions, though he[7] believes the very great reduction in the number of red cells is usually a prominent symptom. Henry[8] believes that the altered relation is due partly to the abnormally large size of the corpuscles, and partly to the fact that the microcytes are not usually counted in estimating the number of red blood-cells present.

Pathological Anatomy.—The cadaver appears well nourished, but the skin is intensely pale and often has the peculiar lemon-tint referred to. Some degree of œdema of the extremities and face is often present, and petechiæ are not uncommonly observed; but all traces of cadaveric lividity and of ecchymoses are usually absent. The subcutaneous fat is abundant. The muscles are pale, or sometimes of an intense deep-red color.[1] The mucous membranes are very pale. The internal organs exhibit an intense anæmia and strongly-marked fatty degeneration. Punctiform or larger hemorrhages are very common in all of the viscera. Moderate effusion into the serous cavities is frequent, and may be hemorrhagic in character. The heart is of normal size or slightly dilated, and contains an unusually small quantity of thin, fluid blood. Its muscle-substance is pale, and exhibits patches of fatty degeneration beneath the endocardium, especially in the left chambers and on the papillary muscles of the mitral valve. The intima of the blood-vessels may also exhibit fatty degeneration. The orifices and valves are usually normal. Cases have been described in which there was found an abnormal narrowness of the arteries. The lungs exhibit no changes beyond the great anæmia, the frequent presence of hemorrhagic spots, and the occurrence of some œdema at their bases. The gastro-intestinal mucous membrane may exhibit œdema and hemorrhage and fatty degeneration of the glands. Atrophy of the gastric mucous membrane has been described in some cases, and I have seen one typical example of it. This may be secondary to the pernicious anæmia, possibly a complication, or possibly a cause of a grave symptomatic anæmia closely resembling pernicious anæmia in its clinical symptoms.

Fatty degeneration and atrophy of the nerve-plexuses of the intestine, probably of a secondary nature, have been described by Jürgens[2] and Sakaki.[3] The pancreas has been found swollen and exhibiting fatty degeneration and hemorrhages. The liver is frequently fatty and sometimes enlarged; it may contain hemorrhages; and Lebert[4] describes the occurrence of leucin and tyrosin in it. The gall-bladder is often very full of bile. The kidneys are pale and show fatty degeneration. The suprarenal bodies have been smaller than normal in some instances.

The brain and spinal cord are extremely anæmic, the cerebral convolutions wasted, and capillary hemorrhages into the white substance often present. The amount of cerebro-spinal fluid is often greater than normal. Hemorrhages may frequently be found on the inner surface of the cerebral dura mater. Lichtheim[5] found the spinal cord intact in no case of pernicious anæmia examined by him. Either small sclerotic foci, the result of minute hemorrhages, were present, or wide-spread degeneration in the posterior columns, extending into the neighboring parts. He believes the degeneration to be secondary to the extreme anæmia.

Alterations of the semilunar ganglion have been described by Brigidi,[1] consisting of an increase of the interstitial connective tissue and of the nuclei, and fatty degeneration of the nerve-fibres and ganglion-cells. Osler,[2] however, found nothing abnormal in two cases. It is doubtful whether the pathological changes in the sympathetic system have any essential connection with the disease.

Retinal hemorrhages have been already referred to as of very frequent occurrence.

Of the organs of the hæmatopoietic system, the spleen may contain hemorrhages and infarcts, but is of normal size or only slightly enlarged. Leucin and tyrosin have been found in it,[3] and nucleated red blood-corpuscles have been observed.

The lymphatic glands are generally normal in appearance. Weigert[4] and Osler[2] have reported cases in which they were of a deep-red color on section, and the former has described nucleated red blood-corpuscles in glands of this character.

The tissue to which the greatest attention has been directed is the marrow of the bones. In many cases the fatty marrow of the long bones of adults is replaced by a red marrow. This change was first described by Wood[5] and afterwards by Pepper;[6] and Cohnheim[7] is inclined to regard it as the specific cause of the disease. There is often, too, a great increase in the number of nucleated red blood-cells. In other instances, however, the marrow has been found of normal appearance.

A feature of the morbid anatomy which has recently sprung into renewed importance is the increase of the amount of iron in various organs, but especially in the liver. In 1876, Quincke found a great increase of iron in the liver in three cases of pernicious anæmia, as shown both by microscopical and chemical examination. This observation was soon after confirmed by Rosenstein.[8] Later Quincke and Peters[9] noticed that this increase was nearly a constant feature. That it is not due to the administration of iron and its subsequent deposition in the liver was shown by the experiments of several investigators.[10] Peters found that the amount of iron may be slightly increased in various diseases other than pernicious anæmia. Hunter has made an extensive and exhaustive study of the subject, and discovered a great excess of iron in the liver in nine cases of pernicious anæmia.

The iron shows itself in the form of altered blood-pigment, occupying the outer and middle zones of the liver-lobules, while the inner circle exhibits only fatty degeneration. This peculiar distribution appears to be characteristic of pernicious anæmia, since in some other affections, in which also the amount of iron is increased, there is no such regularity in its distribution. He regards the excess of iron and the manner of its distribution in the liver as the only constant anatomical lesion to be met with in this disease.

My own observations are not sufficiently extended to justify any conclusions. In three cases I have detected in the liver a great increase of pigment containing iron, and distributed in the manner described. The liver of one of these cases is shown in Plate III., Fig. 11, and more highly magnified in Fig. 12. In a fourth case, however, which during life appeared to be a typical instance of pernicious anæmia, there was no increase whatever of iron. The sections had been in alcohol for some years before being prepared, and I do not know whether it is possible that this long immersion could have dissolved out the pigment. In no other condition, so far as my observations extend, could an increase be recognized, except in one instance,—a curious combination of hepatic cirrhosis, typhoid fever, and ulcerative endocarditis, in which there was during life distinct evidence of a destruction of blood within the system. In this case, however, the increase was but slight, and the pigment exhibited no regularity of distribution.

The method of examination consists in immersing the sections for ten or fifteen minutes or longer in a freshly-prepared solution of ferrocyanide of potassium, and then transferring them, for a few moments only,—with a camel's-hair brush, *not* with a needle,—to a very dilute solution of hydrochloric acid. A well-marked Prussian-blue reaction is thus developed with the iron present. Microscopical examination discloses deeply-stained granules lying within the hepatic cells of the outer and middle zones.

Another method consists in the employment of a fresh solution of sulphide of ammonium, as this darkens all the tissue containing iron. The value of these methods depends on the fact that iron, as contained in ordinary hæmoglobin, does not respond to these reagents, and that it is only after the hæmoglobin has been set free, and has undergone a chemical modification into some other form of blood-pigment, that the blue or black color is produced.

Chemical analyses of the spleen made by Rosenstein,[1] Stahel,[2] each in one case, and by Hunter[3] in nine cases, have shown no marked increase of iron in it. Russell,[4] using simply the micro-chemical method, reports a decided increase of iron in this organ in a case of the disease, the pigment being situated mainly in the walls of the pulp-sinuses.

There is sometimes a deposition of pigment-granules in the kidney, confined entirely to the primary and secondary convolutions of the convo-

luted tubules.[1] The loops of Henle are comparatively free, and the collecting tubes and the glomerules show no trace of pigment.

Pathology.—Whether or not pernicious anæmia is a distinct pathological entity is still a much-disputed question. Henry[2] takes the ground that it is the final stage of several forms of symptomatic anæmia and of chlorosis. The earlier view of Quincke, too, was that pernicious anæmia is merely an extreme condition which may be arrived at in various ways, being simply an anæmia which grows steadily worse and ends fatally. His later view was that the disease has a clinical but no pathological existence. Osler's[3] division of it into groups depending on differences in the pathological anatomy expresses a similar belief. Eichhorst[4] and Coupland[5] divide it into primary and secondary forms. Many writers, on the other hand, believe in the independence of the affection, and, like Immermann,[6] are of the opinion that the so-called instances of the transition of chlorosis or other anæmias into pernicious anæmia are not such, but rather cases in which the latter affection has developed as a complication of the preceding one. Hunter is one of the strongest of the more recent supporters of the independence of the disease, and has done much to establish this. He shows very conclusively that such conditions as the presence of intestinal worms, atrophy of the gastric mucous membrane, and malignant disease, to all of which the disease has been ascribed, are repeatedly met with in cases presenting none of the appearances of pernicious anæmia; and, conversely, that cases of pernicious anæmia are repeatedly seen in which no such changes are to be found. These facts, in connection with the clinical symptoms, but especially with the characteristic condition of the blood during life, and the equally pathognomonic change in the liver found after death, justify the belief that the disease is an independent one due to some cause not operating in other forms of anæmia.

The nature of this cause is another subject still very obscure. The view which has been most commonly accepted is that the blood-changes are due to defective hæmogenesis,—*i.e.*, the affection is to be classed as a cytogenic anæmia. This opinion has been based largely on the changes often found in the bone-marrow, and Cohnheim[7] assumes these as the specific etiological factor. In many instances, however, the marrow of the long bones has been found unaffected, while the characteristic change has been discovered in anæmia of other forms, and has even been produced experimentally in animals by repeated bleedings.[8] Hunter and Eichhorst[9] share the belief that the condition of the bone-marrow is purely secondary,—an evidence of an effort made by the hæmogenic tissue to make up by over-production for the great destruction of the corpuscles. If, now, the bone-marrow be not at fault, we are bound to consider the possibility of the disease being a consumption of the blood, as suggested by Immermann,[1]—that it consists in a direct destruction of red blood-corpuscles, perhaps due to some infectious agents.[2] The exhaustive studies of Hunter are worthy of careful consideration in this connection. This author takes the ground that the excretion of urine of dark color and low specific gravity, containing pathological urobilin; the evidence of an increased secretion of bile, as shown by the dark color of the fæces and the presence of a large amount of bile of dark color in the gall-bladder; the lemon-color or slight jaundiced hue of the skin; and the occurrence of large amounts of altered blood-pigment in the liver, are proofs that a great destruction of the red blood-cells has been going on. He regards the disease as a hæmolytic anæmia. The process differs from that producing hæmoglobinuria in that in the latter affection the disintegration of corpuscles occurs in the general circulation, and the hæmoglobin is excreted as such; while in pernicious anæmia it is carried on in the portal circulation, especially the spleen and liver, and the hæmoglobin set free is carried to the liver and there transformed into an altered blood-pigment and deposited in the liver-cells, or excreted as bile-pigments, producing a polycholia. This increased flow of bile is followed by an increased consistency of it, and this by a stagnation in the bile-ducts; and the attacks of jaundice or the persistence of a slight icteric tint so common in pernicious anæmia are probably to be accounted for in this way. It is possible that the jaundice in some cases may be hæmatogenous. Hunter thinks there is no doubt that the pathological urobilin in the urine is derived, through the medium of the bile-pigments, from the disintegration of hæmoglobin. Hæmoglobinuria does not occur in this disease; but, when the amount of hæmoglobin set free is too great to be disposed of by the liver, it passes through the organ into the general circulation, and is apparently thrown down in granular form within the epithelial cells of the kidney in the process of being excreted. He considers the cause of the blood-destruction to be certain poisons, probably of a cadaveric nature, absorbed from the intestinal tract. This last assumption, as to the cause of the hæmolysis seems to demand further proof; although it has been shared by some writers,[3] and two cases are reported[4] which would seem to favor it, prompt recovery having followed the employment of lavage of the stomach. Hunter admits that in some other affections, as cirrhosis of the liver, chronic venous congestion, and malaria, there may also be a deposit of pigment in the liver, but shows that the seat of the deposition is different. The total absence or slight degree of the iron-reaction in the spleen is to be explained on the ground that, though the blood-pigment is liberated in that organ, it remains hæmoglobin until it reaches the liver, and consequently gives no reaction for iron with the tests employed. Russell,[1] however, does not admit that the liver is the chief seat of the altered blood-pigment in pernicious anæmia, as he has found an increased amount of it in the spleen as well.

Still another view of the nature of the disease has been advanced,[2]—namely, that, although there is undoubtedly a greatly-increased hæmolysis in pernicious anæmia, this occurs on account of *defective hæmogenesis*, which makes the red corpuscles abnormally prone to perish. This theory appears very plausible, especially as the assumption of a cadaveric poison is not altogether satisfactory. In the present state of our knowledge, however, we can scarcely go further than to consider pernicious anæmia a hæmolytic anæmia, the blood-destruction being due to causes unknown; and, as we are not able to prove that it is related in any respect to defective hæmogenesis, it seems best to assign it provisionally to the non-cytogenic group of anæmias.

Diagnosis.—The diagnosis of pernicious anæmia rests on the existence of an extreme and progressing anæmia without evident cause; the absence of emaciation; the peculiar lemon-tint of the skin; the occurrence of hemorrhages; the presence of irregular fever; the condition of the urine, if present, and the characteristic alteration of the blood, this last consisting in decided microcythæmia and poikilocytosis, a very high degree of oligocythæmia, and a relatively large proportion of hæmoglobin. Post-hemorrhagic anæmia, even when severe, does not exhibit the characteristic blood-changes. The urine, too, is usually pale, in contradistinction to the high-colored urine of pernicious anæmia. The secondary anæmias due to cachectic conditions are usually accompanied by wasting. Pure cases of chlorosis are characterized by the condition of the blood peculiar to that disease,—*i.e.*, great loss of hæmoglobin without proportionate diminution in the number of corpuscles. Chlorosis is not infrequently complicated by anæmia, and there is no reason why pernicious anæmia should not be engrafted upon it. This might account for the statement of Bristowe,[3] that it is impossible at the present time to make any trustworthy distinction between the two diseases, except such as depends on the age and sex of the patient and the effects of treatment.

Most of the cases of anæmia attributed to atrophy of the gastric mucous membrane have shown some degree of wasting. Ordinary cases of leukæmia, splenic anæmia, and lymphatic anæmia offer no difficulty in diagnosis. A pure medullary form of the latter must be considered as pernicious anæmia in which the marrow is affected.[1] Myelogenous leukæmia in the early stages may simulate pernicious anæmia, but the examination of the blood after the disease is advanced should settle the matter. Anæmia due to the presence of intestinal parasites may resemble pernicious anæmia very closely, but may sometimes be detected by the discovery of worms or ova in the fæces.

Prognosis; Course; Termination.—The prognosis of pernicious anæmia is most unfavorable. The duration varies from a few weeks to months or rarely years. Statistics do not show that it is more rapidly fatal in children than in adults. Temporary improvement may be witnessed, but the disease is liable to recur. The fatal termination is generally due to the progressing anæmia and consequent debility, with delirium or apathy before death. Pye-Smith[2] gives a table of twenty recoveries, but none of them were in patients under nineteen years of age. Some of these are very probably instances of errors in diagnosis.

Treatment.—As the name of the disease implies, treatment is almost always useless. Proper hygienic and dietetic measures are essential. All dyspeptic symptoms are to be combated with the greatest diligence, and the appetite and strength of the patient maintained by tonics and easily-digested and nourishing food. Defibrinated blood and the prepared beef foods may be found useful, given either by the mouth or rectum. The hypodermic injection of defibrinated blood has even been recommended, and an instance of recovery under this treatment reported.[3] Predigested nourishment will be indicated when the digestive powers seem weak. Cod-liver oil, phosphorus, iron, and arsenic may be given, the latter being the drug on which by far the greatest reliance can be placed. As children bear large amounts of it, the dose should be gradually and steadily increased until the limit of tolerance is reached. Iron is not generally of much value. The unirritating preparations, such as the malate, lactate, albuminate, etc., should be selected if the stomach of the child is delicate. When no other treatment avails, transfusion of blood may be tried, but with doubtful benefit.

ADDISON'S DISEASE.

Synonymes.—Morbus Addisonii, Melasma suprarenale.

Definition.—A constitutional or blood disease characterized by extreme and progressing loss of strength, great debility of the circulation, irritability of stomach, and generally by pigmentation of the skin. In most cases there are degenerative lesions of the suprarenal bodies, usually of a fibro-caseous nature; and in many instances there are changes in the abdominal sympathetic.

---

[1] Birch-Hirschfeld, Patholog. Anatomie, 1883, ii. 1, 153.

[2] Guy's Hospital Reports, 1883, xxvi.

[3] Westphall, Ann. Univ. Med. Sci., 1890, ii. E.

As already stated, the disease can with propriety be referred to the constitutional disorders, or it may be considered here, on the ground that the suprarenal bodies are members of the hæmatopoietic apparatus.

History.—Addison[1] in 1855 gave a clear exposition of the connection of changes in the suprarenal bodies with the symptoms of the disease which bears his name. Previously to this, in 1849, he had announced his discovery to a medical society.[2] Isolated cases had been reported before this time by Schotte[3] and Bright;[4] and since Addison's publication many cases have been recorded, though the affection still remains a comparatively rare one. The case of Schotte's occurred in a girl of fifteen years, and was typical, except that it exhibited no discoloration of the skin. Risel and Greenhow nevertheless consider it a good instance of the disease. Among the valuable articles written on the subject are those of Wilks,[5] Virchow,[6] Averbeck,[7] Bamberger,[8] Gerhardt,[9] Risel,[10] Jaccoud,[11] Greenhow,[12] Burger,[13] Monti,[14] Merkel,[15] Osler,[16] and numerous others, to which full acknowledgment is here made for information and statements drawn from them.

Etiology.—The causes of the disease are unknown. Anxiety, care, unfavorable hygienic surroundings, chronic constipation or diarrhœa, malaria, injuries of the abdomen, etc., have been assigned as predisposing causes in different cases, but it is doubtful whether any of them exert any decided influence. Traumatism of the abdomen has perhaps a little more evidence in favor of its etiological connection with the disease. Persons with a predisposition to phthisis do not appear to be more liable to it than do others. The laboring classes are especially prone to be attacked. The influence of heredity is undetermined. Sex is a strongly predisposing factor, many more males than females having suffered from the disease. Greenhow analyzed 183 cases, of which 119 were males and 64 females; Jaccoud collected the records of 79 males and 48 females with it, and Averbeck 80 males and 46 females. Age, too, is an important factor. The majority of cases occur between the ages of fifteen and forty-five years. In old age and before that of ten years it is exceedingly rare. Out of an analysis of 290 cases Monti[1] found but 11 instances of its occurrence in children under fifteen years. Of these 1 child was aged three years, 1 was aged from ten to eleven years, 3 children were aged twelve years, 1 child was aged thirteen years, and 5 children were aged fourteen years. 8 of the children were boys, and 3 girls. Gerhardt[2] has collected 17 cases in children before the fifteenth year. Besides these Monti[3] has also described another case in a boy of ten years, and Courteen[4] one in a boy of sixteen years. Baginsky[3] quotes Legg and Pye-Smith as having reported cases in boys of fifteen and fourteen years respectively. Probably the youngest case on record is that reported by Belaieff,[5] in a male child seven days old when first seen, who died fifty-three days later with the characteristic symptoms of the malady.

Symptoms.—The disease begins with languor, weakness, and indisposition to bodily or mental exertion, arising without apparent cause, and steadily progressing and becoming excessive. The heart-muscle gradually shares in the asthenia, and the heart's action becomes remarkably feeble. A discoloration of the skin develops usually after the asthenia has lasted some time, though occasionally it is the first symptom noticed. Severe digestive disturbances arise, and grave nervous symptoms may terminate the life of the patient.

Looking at the symptoms more in detail, the alteration of the skin presents itself as the most striking. There is noticed in most cases a gradually increasing pigmentation, at first light yellow, sometimes a greenish-brown or bronzed tint, or perhaps finally almost black. In typical cases the whole surface of the body is discolored more or less uniformly, but certain parts are more deeply pigmented than others; these being the more exposed portions of the body, as the face, the neck, and the backs of the hands; those which have been subjected to pressure, as the waist or the leg from the pressure of a garter; and those which naturally contain considerable pigment, as the areolæ of the breasts, the external genitals, the axillæ, and the flexor surfaces of the joints. In many cases the pigmentation is but slight, and not at all universal. It is not to be regarded as an essential feature of the disease, as many cases have been reported in which it was absent, not only in the rapidly fatal cases, in which there might not have been time for it to develop, but in those as well which had run a more chronic course. The mucous membranes may also become pigmented. That of the mouth may exhibit scattered patches of a very dark color upon the under surface of the tongue, on the palate, and on the gums and the inside of the cheeks and lips. The vagina may be very deeply discolored. The conjunctivæ are rarely affected. The hair, scalp, soles of the feet, nails, and palms of the hands are generally uninvolved. In the case of a child of three years reported by Pitman,[1] the body was covered with a considerable growth of black hairs.

Emaciation is not a characteristic of Addison's disease, though it may occur. Anæmia, too, is not a symptom of it,[2] as even in advanced cases the lips and gums are not bloodless, and the common symptoms of anæmia not often witnessed. The blood is often rich in red corpuscles, and there is no increase of leucocytes.[3] The feebleness of the circulation is remarkable. The pulse is weak, small, accelerated, thready, and often almost imperceptible. The apex-beat of the heart is weak; murmurs are generally absent. The respiration is slightly accelerated, but not generally interfered with in other respects unless complications arise. Attacks of dyspnœa are sometimes observed. The temperature is normal, or very frequently subnormal, except in the very acute cases, in which there may be high fever. Digestive disturbances are characteristic of the affection, and usually appear early in children. They consist in loss of appetite, vomiting or nausea, eructations, cardialgic attacks, annoying hiccough, and, on the part of the bowels, abdominal tenderness and constipation or obstinate and not infrequently fatal diarrhœa. The urine is usually pale and free from albumen. According to Gerhardt, there may be polyuria. The amount of urea may be greatly reduced, and that of indican increased, and in one case Thudichum found the amount of uromelanin much less than normal.[4] Gerhardt and Reichardt[5] discovered traces of taurocholic acid and large amounts of fatty acids in the urine. In a case reported by Nothnagel, and which I had the opportunity of examining, the fatal ending came on suddenly, with mental excitement, delirium, and finally coma; a very large amount of acetone appearing in the urine at the same time.

The most characteristic and constantly present symptoms of Addison's disease are those of the nervous system. Chief of these is the great asthenia,—the complete prostration both of mind and of body, without any other cause than a lack of nervous energy. The prostration finally becomes so extreme that the patient cannot sit upright, the voice becomes weak, and the limbs tremble when raised.

Among other nervous symptoms may be mentioned the frequent and sometimes early occurrence of pain in different parts of the body; as headache, and pain in the back and abdomen and in the limbs. The pain in the joints may simulate that of rheumatism. Tenderness on pressure in the lumbar region is often noticed, and is probably due in many cases to the formation of abscesses in front of the spinal column. Pain would appear to be a little less constant symptom in children, as Monti found it in only three of the eleven cases analyzed by him.

[5] Eichhorst, Spec. Path. u. Therap., 1885, ii. 622.

As the disease advances the intelligence grows dull, the memory weak, and sleepiness or delirium may be observed. Attacks of fainting, dizziness, dyspnœa, or palpitation become more frequent, and are evidently due to the nervous disturbance rather than to anæmia. Maniacal attacks have been witnessed. Coma or convulsions may supervene and perhaps produce the sudden death of the patient. Children are particularly liable to exhibit convulsions of varying intensity, from slight twitching of the muscles to well-marked epileptoid convulsions. Gerhardt states that two-fifths of the cases collected by him suffered from convulsions.

Pathological Anatomy.—The fatty tissue of the body is not materially diminished in amount; the muscles are not pale. The skin presents the dark discoloration described. On microscopical examination there is found an increase of the pigment in the deeper layers of the cells of the rete, and, in well-marked cases, in the papillary layer of the cutis and even in the connective-tissue cells. It does not differ in nature and arrangement from the pigment seen in the skin of the negro.

The most interesting pathological change is that occurring in the suprarenal bodies. By far the most constant lesion presented by them is a fibro-caseous condition. They are much larger than normal, hard on section, irregular and often nodular in shape, and frequently adherent to surrounding structures. The normal tissue of the gland is replaced by a firm, somewhat translucent, homogeneous substance, in which are embedded yellowish or grayish, cheesy nodules of the size of a pea or larger. These masses may either be transformed into calcareous nodules or may undergo softening and form pus. In the early stages of the disease the tissue of the gland is, according to Wilks, nearly or entirely replaced by the homogeneous substance referred to. The cheesy foci develop later, and in advanced stages may completely substitute the homogeneous material first deposited.

Microscopical examination shows the translucent substance to be composed of fibrous tissue, either in a young or a more advanced condition. The yellow nodules consist of masses of detritus. When degeneration has not become complete in them, they exhibit a growth of small cells contained in a delicate reticulum. Giant cells are sometimes present. The lesions are very similar to local tubercular affections. Tubercular bacilli have been found in many cases, but not discovered in probably as many others.

The fibro-caseous change is not, however, the only one which has been found in Addison's disease. Carcinoma has occurred in rare instances, and produced the symptoms of the affection. This is said to have been the case in the child of three years recorded by Pitman.[1] Sarcoma of the suprarenals with the symptoms of Addison's disease has been reported. Simple atrophy of the capsules has also been present in this disease, as have amyloid degeneration, interstitial hemorrhages, or gummata in them.

The condition of the abdominal sympathetic is a matter of great importance. The semilunar ganglia have exhibited a hyperplasia of the connective tissue in a number of cases, with degeneration and pigmentation of the nerve-cells. The nerves leading from the ganglia have been found degenerated in some cases, and in others normal. Jürgens[2] claims that a gray degeneration of the splanchnic is present in a large proportion of the cases, whether or not there has been disease of the capsules.

Of the other organs of the body the heart has been found very small in some instances, and its muscle degenerated to some extent. The spleen and thymus gland are sometimes enlarged. The lymphoid elements of the intestine, as seen in the solitary glands and in Peyer's plaques, are very commonly swollen, and ulcers in the ileum may be present, and the lymphatic glands of the retro-peritoneum and the mesentery may also be swollen and perhaps cheesy. Lymphoid deposits have been observed in the stomach. The lungs are tubercular in a large number of cases, and the bronchial glands cheesy.

Pathology.—As we do not know the function of the suprarenal bodies, we cannot well understand the pathology of Addison's disease. Osler gives a lucid exposition of the chief of the different theories which have been suggested. These are—

1st. The view of Addison,—that the disease is directly dependent on a destruction of the capsules and the consequent cessation of their functions. According to this view, the pigment accumulates in the blood, it being the function of the glands to destroy a substance in the blood which is readily converted into pigment. Taylor[3] believes that the pigmentation is induced by the destruction of the cortical portion of the gland, and the nervous symptoms by the involvement of the central portion, as this is in such close relation with the nerve-structures. The objection to this theory is that cases are reported in which the suprarenal bodies exhibit no change, and that removal or destruction of the bodies in animals is not followed by the symptoms of the disease.

2d. The belief that the disorder is an affection of the abdominal sympathetic, induced usually by disease of the suprarenal bodies, but also by other affections. This theory is accepted by probably the majority of writers, and would seem to explain the symptoms better than any other. While there are many arguments in its favor, there are certain powerful objections to it. It is, namely, uncertain what the changes in the sympathetic ganglia and nerves are in many cases; and in others it seems quite positive that no pathological changes at all existed in them. It is also difficult to understand why the symptoms of Addison's disease are not produced in the many instances in which the semilunar ganglia are very greatly implicated by other affections than disease of the suprarenal bodies. Thus, in aneurism of the abdominal aorta and retro-peritoneal cancer no bronzing of the skin is, as a rule, observed.

[2] Deutsche Med. Zeitung, May 10, 1888.

[3] New York Medical Journal, 1856.

3d. The view, for which there is no good support, that the disease is due to some poisonous agent introduced from without, or the result of imperfect metabolism.

4th. A theory allied to the first,—that the blood is gradually poisoned by the retention of some material the destruction or alteration of which it is the function of the suprarenal bodies to effect. From this point of view the disease is analogous to chronic uræmia.

In any case it does not seem justifiable to assume, as Wilks and others have done, that that only can be called Addison's disease in which the degeneration of the glands is of a fibro-caseous nature. Rather is the affection not a definite anatomical disease so much as a peculiar aggregation of symptoms.[1] If it depends solely on a lesion of the suprarenal bodies, this lesion might well be of any nature which would accomplish their destruction. If, on the other hand, it is due to a disturbance of the function of the abdominal sympathetic, there would seem to be no reason why this must depend on a lesion of the suprarenal bodies alone.

Complications and Sequelæ.—The only one deserving of notice is tuberculosis of various organs, which is of very common occurrence. Oppenheim[2] reports a case complicated by exophthalmic goitre.

Prognosis; Course; Duration.—The prognosis is absolutely unfavorable, if the diagnosis of the disease has been correctly made. Gull[3] and Finney[4] report cases of recovery. The course of the disease is onward until life is terminated slowly and quietly by the asthenia. Sometimes convulsions, syncope, coma, or diarrhœa cut the affection short. Tubercular complications are very seldom the cause of death. The duration of the disease is very variable. The course may be very acute and resemble that of typhoid fever to some extent. In such cases the affection begins with high fever, vomiting, diarrhœa, and excessive prostration, which rapidly grow worse until death occurs in a few weeks or months. In other cases this rapid course may change into a more chronic one, and in still others it may be chronic from the beginning, and the patient live for several years. Temporary remissions occur and last some months, during which time there is either improvement or cessation in the progress of the symptoms.

Diagnosis.—The diagnosis is easy if there be present the combination of the nervous symptoms with the coloration of the skin. Pigmentation of the skin alone is not, however, a diagnostic symptom. It may be quite deep and intense in abdominal growths, but is not usually so uniform as in Addison's disease. In tubercular peritonitis, however, it may be very marked.[1] In hepatic diseases spots of pigment are often seen about the face. A wide-spread pigmentation has been reported in persons suffering from melanotic growths, and might render a diagnosis uncertain.[2]

The pigmentation of pregnancy and of uterine disease does not, of course, come into consideration in a work of this nature. In persons of uncleanly habits the irritation of pediculi may cause a pigmentation resembling that of Addison's disease, but the presence of the parasites or of the scratches and the white cicatrices should make the diagnosis plain. Argyria is known by the history; intense icterus by the condition of the conjunctivæ; cyanosis by the disappearance of the color on pressure.

Treatment.—Treatment, except that directed to the symptoms, is useless. Absolute rest is to be enjoined, to avoid the danger of syncope. The best of food and the employment of stimulants are indicated to support strength, and tonic drugs may be given for the same purpose. Diarrhœa and vomiting need treatment appropriate to them. Arsenic, strychnine, iron, cod-liver oil, phosphorus, quinine, have all been recommended, and may accomplish temporary good. Morphine will be needed in some cases. Strong purgative medication should never be given to relieve constipation, as there is danger of collapse following. Galvanism, counter-irritation, and the administration of iodide of potassium or syrup of the iodide of iron ought to be tried.

INFECTIOUS HÆMOGLOBINÆMIA OF THE NEWLY-BORN.

Synonymes.—Epidemic hæmoglobinuria of the new-born (Birch-Hirschfeld), Acute hæmoglobinæmia of the new-born (Hirst), Cyanosis afebrilis icterica perniciosa cum hæmoglobinuria (Winckel), Epidemic hæmoglobinuria with icterus in the new-born (Runge), Maladie bronzée hématique des nouveau-nés (Laroyenne and Charrin), Tubulhématie rénale (Parrot), Maladie bronzée hématurique des nouveau-nés (Bar and Grand'homme), Winckel's disease.

Definition.—An acute and usually epidemic affection of the blood, developing in the newly-born, characterized by cyanosis, icterus, and hæmoglobinuria, running a rapid course and ending fatally in almost every instance.

[2] Wagner, Archiv d. Heilkunde, 1864, v. 280; Legg, Trans. Path. Soc. London, 1884, xxxv. 367.

History.—In 1871, Pollack[1] gave a brief report of twelve sporadic cases which he had observed within the year, and which would appear very probably to be instances of the disease under consideration, though none of them are individually described.

In 1873, Laroyenne[2] described an epidemic of the disease which occurred in the Maternity Hospital at Lyons, and in which fourteen infants were attacked; and his pupil, Charrin, later made the affection the subject of a thesis.[3] Very shortly after Laroyenne, Parrot[4] reported two cases seen by him not occurring at the same time. Two years afterwards, in 1875, Bigelow[5] gave an account of an epidemic seen in the Boston Lying-in Hospital, in which ten infants were affected. In 1877, Herz[6] published two cases which he denominated "acute fatty degeneration of the new-born," but which appear to be doubtless instances of the disease now under consideration.

By far the fullest description of the malady is that of Winckel,[7] in 1879. Twenty-four children in the Dresden Maternity Hospital were attacked by it in the course of little more than one month. He called it a "hitherto undescribed endemic disease of the newly-born;" and it is probably on this account that the disorder has usually and unjustly gone by his name. Some additional remarks on its pathological anatomy, based on some of these cases, were afterwards published by Birch-Hirschfeld.[8]

Epstein[9] states that he has observed cases in the Prague Foundling Hospital similar to those described by Winckel. Baginsky[10] says that he has seen a typical example of the disease, but I have not been able to find any further description of it. Sandner[11] gave a careful description of a case seen by him in 1886, and Bar and Grand'homme[12] and Strelitz[13] each reported one seen in the year 1889, and Hirst[14] one in 1890.

Etiology.—The cause of the disease is very obscure. No condition of the mother is recorded which could have produced the disease in any of the cases. The only possible, though altogether improbable, exception is in the two cases of Herz's, in which the fact is to be noticed that both were children of the same parents.

Only one of Winckel's twenty-four cases was born with instruments; eighteen of the cases were fed only on the breast-milk; the possibility of poisoning having taken place was excluded by the careful chemical examination of the organs; and the children were not in any way exposed to cold. The same total absence of discoverable cause existed in the cases of Laroyenne and Charrin's. The influence of extremes of cold and heat in producing hæmoglobinuria has been shown by Ponfick,[1] and two of the cases reported illustrate a possible connection between these factors and the disease,—the patient of Strelitz's, namely, had the operation of ritual circumcision performed in a quite cold room, and Hirst's case had suffered several burns on the legs and buttocks from the too close application of hot-water cans shortly after birth. There is reason to believe, however, that in both instances other causes were more probably active.

The disease attacks the vigorous as readily as the feeble child. In Pollack's rather doubtful cases severe intestinal catarrh preceded the discharge of bloody urine. In very few instances could the existence of any focus be discovered from which the absorption of septic matter could have taken place. The wound on the penis of Strelitz's case was perfectly free from pus. In nine of Bigelow's patients there was a diphtheritic inflammation of the mucous surfaces, which developed, as a rule, on the same day with the discoloration of the skin, and can hardly be said to have clearly stood in any causal relation to the cyanotic disease. The same statement applies to the appearance, in Parrot's cases, of "*muguet*" on the buccal mucous membrane some days after the symptoms of the disease had appeared. There is no record of the existence of any septic process in the umbilical wound in any instance, unless it be in one of the cases of Bigelow's, and there is no evidence that this antedated the appearance of the characteristic symptoms. In both of Herz's cases, however, a diphtheritic deposit appeared on the palate some days before the constitutional symptoms developed.

Symptoms.—The disease begins in most cases with a very marked degree of restlessness, a refusal of the child to nurse, and a wide-spread cyanotic discoloration of the skin, combined with a more or less icteric hue. In other cases apathy replaces the restlessness, and in some instances convulsions are among the earliest symptoms. The skin is usually cool, but may be hot; the pulse and respiration are often accelerated. Urine of a dark and often coffee color is voided, and makes a brown or greenish stain on the diapers. As the disease advances, the discoloration of the skin becomes extreme, convulsive movements of some sort are liable to appear, and the child dies in a few hours or days with convulsions and in collapse.

The age at which the symptoms first appear is subject to some variation. Bigelow gives the average age at about eight days. Winckel says the disease develops at about the fourth day of life, though in one of his cases it began on the first day, and in one on the twelfth. Pollack states that all of his twelve cases developed within the first six weeks of life. The symptoms in Strelitz's patient did not show themselves until the ninth or tenth day, and the discoloration of the skin in one of Herz's cases not until the eleventh day and in one of Parrot's cases not until the twelfth day.

---

[1] Verhandl. d. Congr. f. innere Med., 1883.

Looking at the symptoms more in detail, the peculiar tint of the skin is very striking, that of the visible mucous membranes being somewhat of the same sort. It has been variously described as violet (Laroyenne), olive-green or like the color of a bruise (Pollack), color of old copper or olive-bronze (Bar and Grand'homme), bluish (Winckel), brownish black (Sandner), bronze or a mixture of yellow and violet (Parrot), brownish green (Hirst), etc. These differences clearly depend upon the varying proportions of cyanosis and of icterus present. The cyanosis is probably nearly always the predominant feature.

Equally important with the discoloration of the skin is the altered condition of the urine. Its color varies from pale brown to that of coffee-grounds. This alteration was clearly shown in the cases of Winckel's, Hirst's, and Epstein's to be due not to the actual presence of blood in the urine, but to its liberated coloring-matter, either as hæmoglobin or some modification of it, since no or but few red blood-cells were found. In Parrot's cases it would seem that there had been some degree, at least, of hæmaturia, and the same remark applies to the cases of Pollack's. Hæmaturia is ascribed to Bigelow's and Herz's cases, while Sandner describes the urine in his case as that of hæmoglobinuria, though no microscopical or chemical examination was reported in any of them. Strelitz speaks of the violet-brown stain made by the urine on the diapers, and Bar and Grand'homme of the dark-brown coloration produced in the same way, but in neither case was an examination of the urine made. Winckel reports some albumen, renal epithelium, and brownish granular casts. Pollack found a small amount of albumen, renal epithelium, blood-cells, and casts filled with blood-cells. Epstein reports much albumen, and epithelium and epithelial casts containing hæmatoidin crystals. Both Winckel and Epstein observed the presence of micrococci in the urine. The urine in Hirst's case contained albumen and some shells of corpuscles. Parrot found brownish granules and the débris of corpuscles. No bile was present in the urine in the cases of Winckel's, and no other observer refers to this matter. The urine in Herz's and Winckel's cases was voided frequently, and in the latter instance in small quantities and with straining efforts. In one of Parrot's cases but small amounts of urine are said to have been passed.

The nervous symptoms of the disease are of interest. Very frequently among the early symptoms is a peculiar irritability and restlessness. Pollack calls attention to this, and it was noticed also in the cases of Winckel's, Strelitz's, and Bar and Grand'homme's. Convulsions of an epileptoid nature occurred frequently in one of Parrot's cases during eleven days before the affection of the skin and of the urine appeared on the twelfth day of life. These were probably entirely independent of it. Convulsive movements are very commonly present in the course of the disease, as seen in the extremities, as twitchings and trembling of the eye-muscles, rolling of the eyes, strabismus, and finally as general convulsions (Winckel). Strelitz reports the presence of trismus in his patient. Sandner observed apathy at the beginning of the disease, changing later into somnolence. Winckel refers to the evident somnolence and stupid condition seen in several cases. Parrot's first case, too, went into a comatose condition as the characteristic symptoms of the disease developed, as did one of Herz's patients. Sighing and moaning have been noticed in several instances (Laroyenne, Bigelow, Winckel), and Strelitz's patient occasionally uttered loud cries. Both of Herz's patients passed into a state of collapse with the sudden onset of the disease. Nervous symptoms may, however, be absent or slight. Bigelow makes no mention of any, and Laroyenne and Charrin saw no cerebral phenomena in any case.

The temperature varies in different cases, though it would appear to be usually normal or subnormal. Winckel uses the word "*afebrilis*" in his definition of the disease. Epstein, on the other hand, states that in diseases of the newly-born frequent and great variations in temperature are apt to take place. Consequently the presence of fever may be easily overlooked in this disease unless records are taken at short intervals. In one patient of Winckel's the temperature reached 100.5° F., but in all the others it ranged from 97.5° to 99.2° in the rectum. In one of Parrot's cases the temperature reached 102° F., but fell to 93.2° some hours before death; while in the other case the temperature was usually about normal, rising only once to 100.4°. In one of Herz's cases there was decided lowering of the temperature; in the other it equalled 104.9° F. at first, but was much depressed later. The temperature of Hirst's patient was normal until the day before death, when it reached 102° F.; and that of Strelitz's patient equalled 101.2° on the day before death. Other reporters of cases make no definite statements regarding the degree of temperature, excepting that Laroyenne states it to be lowered several degrees in the last hours of life. It would thus appear that there is a tendency in infectious hæmoglobinæmia to a depression of temperature, but that some elevation of it may be present without militating against the diagnosis, as would be the case did Winckel's statement hold good.

Regarding the symptoms appertaining to the digestive apparatus, one of the most prominent is probably the partial or total indisposition or inability to nurse which developed early in a large number of cases, as in those of Bar and Grand'homme's, Pollack's, Hirst's, and some of Bigelow's. In the patient of Sandner's and in those of Herz's swallowing is described as difficult or impossible. An ulceration of a diphtheritic nature appeared on the hard palate of both of Herz's cases soon after birth, and a diphtheritic inflammation of the mouth was present in nearly all of Bigelow's patients. In both of Parrot's cases an affection of the oral mucous membrane was present which is described as thrush ("*muguet buccal*"), but the exact nature of which remains a matter of doubt. Thrush is mentioned in three of Winckel's patients. Repeated vomiting was noticed in the patient of Bar and Grand'homme's and in a number of Winckel's cases.

The fæcal passages are usually altered in color and incline towards diarrhœa. Bigelow draws especial attention to this point, having found dark-greenish and offensive stools in eight of his ten cases. Fæces of this same dark-green color, sometimes accompanied by mucus, were noticed by Laroyenne and Charrin, Parrot, Herz, and Strelitz. Winckel describes the passages as ochre-yellow or brownish, and seldom diarrhœic. The diarrhœa preceding the development of the symptoms in the cases reported by Pollack can scarcely be regarded as a symptom of infectious hæmoglobinæmia.

The respiration varies in different cases. It has been described as accelerated by Strelitz, Sandner, and Herz; and decided dyspnœa was observed by Winckel in a number of instances, as well as by Parrot in both of his patients. On the other hand, Bar and Grand'homme describe the respiration as not increased in frequency, and in one of Bigelow's patients it was even slower than normal.

The pulse is, as a rule, little, if at all, altered. This was the case in the patients of Sandner's, Bar and Grand'homme's, and Winckel's. Laroyenne, on the other hand, describes it as rapid in his cases, and Herz found it small and impossible to count in one of his. Parrot, too, could not count it in the early stages of the disease in one instance.

The condition of the blood is a matter of great interest. Laroyenne says that it is brownish black when drawn from the finger, with the number of leucocytes and the volume of the red cells increased, and "granulations" present. Parrot found the number of erythrocytes in one of his cases equalling 1,700,000, with a ratio to the leucocytes of 48 : 1. In the other the number of erythrocytes was only 1,140,000. In the second case the blood as drawn from the finger was clear. In the first, however, it was very dark, and like pitch. The leucocytes were larger than normal, and very many of the red cells greatly altered in shape; some being of great size, some having a sort of nucleus, or being flattened or lengthened, or shrivelled and small and containing a small or large number of granules. Similar granules were found free in the plasma, either isolated or in groups. In one of the veins of the kidney Bigelow found the ratio of white to red cells equalling 1 : 20. Winckel describes the blood as syrupy, dark brown or grayish brown in color, and containing a decidedly increased number of white blood-cells of a larger size than normal, and numerous granules. Strelitz examined the blood from the heart of his patient twelve hours after death, and found it brown-red and with almost no normal red cells. Those still containing hæmoglobin were irregularly shaped, or only in the form of fragments of corpuscles, or apparently grouped in masses. Most noticeable was the very large number of "shadows,"—the corpuscles which had lost their hæmoglobin. Cultures made from the blood revealed the presence of a coccus. Birch-Hirschfeld found cocci in the blood of one of Winckel's cases. The number of red blood-cells in Hirst's patient was reduced rapidly from 5,700,000 to 3,400,000, or 61 per cent., while the hæmoglobin equalled 89 per cent.,—a noteworthy fact, which appeared to indicate the presence of free hæmoglobin in the circulation. The ratio of white to red cells equalled 1 : 13.5. Poikilocytosis was very marked. Culture experiments made with the blood of this patient taken before death revealed a coccus, the exact nature of which is not yet determined.

Of symptoms only exceptionally observed may be mentioned enlargement of the liver and spleen (Herz); numerous metastatic abscesses, with diphtheritic inflammation of the vulva (Bigelow); inflammation of the eyes (Bigelow); opacity of the cornea (Parrot); erysipelas of the scalp (Parrot); tenderness in the renal region (Pollack); alteration of the size of the pupils (Parrot, Sandner); bronchial râles, irregular respiration, continuous flow of saliva (Winckel).

Pathological Anatomy.—The color of the skin and mucous membranes persists after death, though sometimes it is not so intense, and the internal organs exhibit more or less of an icteric color. The chief interest centres on the condition of the urinary organs. Winckel, who has made a much larger number of autopsies than any other one observer, describes the kidneys as not enlarged; and no contradictory statements are made excepting by Pollack, who considers them larger than normal. The color of the organ is variously stated. Pollack described the cortical substance as dark brown, while in the pyramids could be seen dark lines, which he considered to be clots, the extension of large thrombi present in the renal vein. That these lines were true thrombi is not certain. Similar black lines have been remarked by Parrot, Sandner, Hirst, Bar and Grand'homme, and Winckel. Strelitz considered it a very characteristic feature, and depicts it in a lithographic plate. Laroyenne describes the kidneys as chestnut-colored; Hirst as cyanosed, and the cortical and medullary layers well separated. Strelitz says they are dark brownish red, and that the two portions are not well distinguishable. Herz describes the cortex as pale, Sandner as dark red, and Winckel as widened and of a brown color. Parrot calls the kidneys pale cinnamon, with rose-colored spots and evidences of foci of softening; the pyramids being brownish red and exhibiting the dark lines referred to. It is evident that the only characteristic pathological appearance in the kidney, discoverable by the naked eye, consists in the presence of these dark lines.

Ecchymoses are often present under the capsule or in the cortex (Herz, Winckel, Sandner). Coagula or black or dark-green masses of considerable size are often found in the calices, pelvis, and in the bladder (Parrot, Bigelow, Laroyenne, Herz, Sandner, Bar and Grand'homme). The description of the microscopical appearance of these masses in the different cases is approximately identical with that given by the different writers of the substance found within the tubules of the kidney. A further account of them will therefore not be necessary.

A microscopical examination of the kidney reveals the presence of masses of a yellow or a nearly black color filling many of the ducts of Bellini and the blood-vessels, as well as the convoluted tubules in some cases, but seldom involving the capsules. Parrot described these masses as without doubt made of corpuscles, although he admits that in many tubules not the slightest form could be discovered which resembled a corpuscle. In some of the tubules, however, he detected genuine blood-casts, while the veins in the kidney could be seen distended with corpuscles. Bigelow describes the substance in the convoluted tubules and the ducts of Bellini as a gray or brown granular mass with no trace of blood-disks, and containing granules of hæmatin. Herz speaks of coagulated blood in the tubules, but gives no details of any microscopical examination of it. Bar and Grand'homme state that the convoluted and the straight tubules are filled with a finely granular exudate containing some deformed red globules. Epstein describes hæmatoidin infarcts in the kidney, and Winckel, Strelitz, Sandner, and Hirst agree that the granular matter is partly or chiefly made up of hæmoglobin, containing few or no blood-cells. I have treated sections of the kidney from Hirst's case with potassium ferrocyanide and hydrochloric acid, in the manner employed by Hunter for the recognition of iron in pernicious anæmia. Thus prepared, the cortex exhibited numerous brightly-colored tubules, the result of the formation of Prussian blue out of the altered blood-pigment present. The glomeruli remained unstained. As hæmoglobin will not respond to this test for iron, it would seem that it must have undergone some further change into an altered blood-pigment. The condition of the renal epithelium varies in different cases, sometimes being entirely unaffected (Pollack), oftener exhibiting some cloudy swelling and perhaps extensive desquamation (Herz, Strelitz, Hirst, Sandner) or fatty infiltration (Winckel). Micro-organisms were present in the kidney in some cases (Bigelow, Winckel, Strelitz, Hirst, Bar and Grand'homme), sometimes within the tubules, sometimes in the blood-vessels, sometimes scattered throughout the substance of the organ.

Parrot describes the liver as of normal color and size, and Laroyenne states that it was of a brown color and on section did not redden; but he makes no further observation regarding it. Bigelow found it normal in all except one instance, and in this there were alterations resembling those of yellow atrophy. Other observers who refer to its condition, though mentioning no special alteration in size, and though attributing different colors to it, uniformly describe a microscopic alteration of the parenchyma, consisting of cloudy swelling or fatty degeneration of varying intensity. This was noted by Herz, Winckel, Sandner, Strelitz, and Hirst. Small ecchymoses under its capsule are described by Winckel. Sections of the liver, which I had prepared from Hirst's case, showed very decided changes in the parenchyma, the cells being very decidedly granular and indistinct, and the nuclei for the most part invisible. Treated with ferrocyanide of potash, the liver exhibited a decided increase in the amount of iron, but not by any means so great as in pernicious anæmia, nor was the pigment distributed with the same regularity.

The spleen is reported as enlarged,—often very greatly so,—and as dark or almost black, by nearly all writers. Only Bar and Grand'homme speak of it as of normal size, though noticing the black color. It is also said to be congested (Hirst), to contain pigment-granules (Hirst, Strelitz), to be filled with red blood-cells (Sandner), and to exhibit hemorrhages (Herz). Numerous small groups of cocci were found in it by Hirst.

The lungs are described as black by Laroyenne, and as black-red and œdematous by Sandner. In both of Parrot's cases they exhibited points of hepatization, and in Hirst's patient numerous infarcts. Ecchymoses are not uncommon on the pleura (Strelitz, Herz, Winckel). Herz describes the mucous membranes of the respiratory passages as reddened. A diphtheritic deposit was found in the larynx in some of Bigelow's cases, and enlargement of the bronchial glands by Winckel.

Winckel says that the heart-muscle was fatty in most of his cases, and Hirst has confirmed this observation in his patient. Laroyenne and Sandner found respectively a chocolate-colored and a dark-red fluid in the pericardial sac, while Herz describes it as icteric in his case. Winckel refers to the presence of ecchymoses on the pericardium and sometimes on the endocardium.

As regards the digestive apparatus, Bigelow found a diphtheritic deposit in the œsophagus in one instance. Swelling, injection, and ecchymoses of the mucous membrane of the stomach and intestines are described by Winckel, and Sandner also refers to the ecchymoses in the gastric mucous membrane and the presence of a few small black coagula in the cavity of the stomach. Winckel found the mesenteric and inguinal glands enlarged, and patches of ecchymoses on the peritoneum.

Among other post-mortem lesions noticed may be mentioned foci of softening in the brain, apparently independent of the hæmoglobinæmia (Parrot), a chocolate-colored cerebro-spinal fluid (Laroyenne), and minute ecchymoses on the meninges of the brain (Winckel). Obstruction of the renal veins by clots is described by Pollack and Parrot, and thrombophlebitis of the umbilical vessels in one instance by Bigelow. The latter also noticed diphtheritic membrane on the vulva in one case.

Pathology.—In the absence of a fuller knowledge of the etiology of the disease, no positive conclusions can be drawn regarding its pathology. Pollack claimed that as the result of an exhausting diarrhœa thrombosis occurred in the renal vein, and that this was the immediate cause of what he designated hæmaturia. Parrot, however, showed that the lesions and symptoms were essentially different, since no blood was present within the tubules after thrombosis, and discoloration of the skin never, in his experience, accompanied it. The possibility also exists of exposure to cold being the cause of hæmoglobinuria in Strelitz's case; and the occurrence of burns in that of Hirst's. But the similarity of the symptoms and post-mortem lesions in all the different cases points to a more generally acting etiological factor.

One of the most impressive features regarding the pathology of the disease is the fact that in the great majority of cases it has occurred endemically. This was true in the fourteen cases reported by Laroyenne and Charrin, the ten of Bigelow's, and the twenty-four of Winckel's. Facts such as this render it almost certain that the malady is of an infectious nature. The development of diphtheritic processes in the cases of Herz's and of Bigelow's, and possibly also in those of Parrot's, is an additional proof of this. The nature of this infection and the manner in which the child acquires it are still matters fully unsolved. In no instance has the mother of the affected children suffered from any septic puerperal processes.

In almost every instance, too, no wound could be found on the child which exhibited any unhealthy condition. It is to be remembered, however, that every child during the first few days of life possesses an open wound,—the umbilicus,—through which infection may be acquired, and it may be that this can happen even when the wound shows no abnormal appearance. In the absence of infection by this channel, the possibility of this taking place by way of the digestive tract must be taken into consideration. This is the explanation adopted by Winckel for the origin of the disease in his patients, and it would seem that Pollack's cases may be explained in the same way.

Finally, the infectious nature of the disease in question is sustained by the discovery by several observers of micro-organisms in various parts of the body. These microbes are certainly cocci,—except in the case of Bar and Grand'homme's, in which bacilli were also found,—but whether pathogenic or some septic form is not yet known. Strelitz, who has made very careful bacteriological studies in his case, comes to the conclusion that the microbes found by him are to be placed in the group with the streptococcus pyogenes. Smith, in studying Hirst's case, concludes that the organism is the streptococcus pyogenes, while Hatch, in the same case, expresses the belief that, though very similar, it is not identical with it.

Assuming that the disease is infectious, we can readily understand its true nature,—viz., a rapid destruction of the red blood-cells within the vessels, due to the presence of the toxic agent, and producing hæmoglobinæmia, and the consequent hæmoglobinuria, cyanosis, icterus, and ecchymoses. That we have indeed to do with hæmoglobinæmia was evident in the cases of Winckel's, Epstein's, and Hirst's, and Strelitz and Sandner also attribute the symptoms to hæmoglobinæmia; and, though Bigelow and Bar and Grand'homme speak of hæmaturia, yet their descriptions of the renal changes show the truly hæmoglobinæmic nature of the affection. Herz mentions hæmaturia, but his observations are not at all complete. The cases of Pollack's and Parrot's undoubtedly exhibited blood-cells in the urine and kidneys, and probably in considerable quantity. The blood, however, was certainly in a greatly altered condition, and it is exceedingly probable that the abnormal color of the urine was due in great part to the excretion of the altered coloring-matter of the corpuscles. It is possible that the poison acted also upon the walls of the blood-vessels or upon the red blood-cells in such a way that the latter were able to pass out of the renal capillaries in some numbers, while at the same time the majority were destroyed in the circulation and their coloring-matter excreted in the urine.

Diagnosis.—The question has been raised whether infectious hæmoglobinæmia is not identical with acute fatty degeneration of the new-born, described by Buhl in 1861; and the diseases do, in fact, present many points of similarity. In Buhl's disease, however, the infants are usually born in an asphyxiated condition without any adequate discoverable cause for this, and then either die or rapidly develop the symptoms of that disease. Hæmoglobinuria does not occur in it. Hemorrhages from the stomach and bowels and often from the navel, and extensive extravasations of blood into the skin, mucous membranes, and various organs, and the much more chronic course, also serve to distinguish it from infectious hæmoglobinæmia. The autopsy, too, is said to reveal a constant and much more extreme fatty degeneration of the various viscera. One cannot, however, but be impressd with the close resemblance, in many particulars, existing between the two diseases. The reported cases of acute fatty degeneration are too few in number, and the condition too little understood, to determine positively the question of its relation to, or identity with, infectious hæmoglobinæmia.

Infectious hæmoglobinæmia is further to be distinguished from poisoning by potassium chlorate, carbolic acid, and phosphorus. The diagnosis of the affection from poisoning by potassium chlorate must rest very largely on the absence of the possibility of the occurrence of the latter, as the symptoms are very similar. Thus, in poisoning with the chlorate there is cyanosis and often icterus, and the excretion of a dark urine containing hæmoglobin or methæmoglobin and brownish casts exhibiting remnants of red blood-cells. The blood is chocolate-colored and gives the spectrum for methæmoglobin, and many of the corpuscles have lost their coloring-matter. The tubules of the kidneys examined post mortem are found filled with brownish casts, and ecchymoses are frequent in the different mucous membranes. Nevertheless, as distinguishing poisoning with the drug are the greater frequency of dyspnœa, vomiting and diarrhœa, and the presence in many cases of small ecchymoses over the surface of the body; while after death the liver is found enlarged and filled with brown matter, the result of the disintegration of the corpuscles.

Carbolic-acid poisoning may be present in the newly-born, due to the employment of the acid about the mother or the child. It may simulate infectious hæmoglobinæmia to some extent in the dark-colored urine and the cyanosis. The blackish or blackish-green urine, however, is not, as a rule, due to hæmoglobinuria. When it is treated with nitric acid and then with potash it becomes reddish, then pea-green, and finally violet. Without this peculiar character of the urine the case is not one of carbolic-acid poisoning.[1] Further, dyspnœa is excessive in poisoning by carbolic acid, vomiting and purging are common, and convulsions are exceptional.

Poisoning with phosphorus, which may also in some points bear a close resemblance to infectious hæmoglobinæmia, is scarcely to be expected in children so early in life. Usually one of the first and most constant symptoms is vomiting, and the vomited matter smells strongly of phosphorus and exhibits a phosphorescence in the dark. The stools are light-colored and rarely bloody. Icterus commences only after from thirty-six hours to several days, and is accompanied by dermal hemorrhages, but not by cyanosis. Fever of slight degree is usually present. Enlargement of the liver may often be detected. Hæmoglobinuria rarely if ever occurs, but the urine often contains bile and blood, nearly always sarco-lactic acid, and sometimes sugar, fat, leucin, and tyrosin. At the autopsy the liver is generally found to be greatly enlarged, and to have undergone extensive fatty degeneration resembling the condition of acute yellow atrophy; and there is wide-spread fatty degeneration throughout the tissues of the body. All these symptoms are in sharp contrast with the rarity of vomiting and the absence of enlargement of the liver in infectious hæmoglobinæmia, and the presence of tarry stools, rapidly-developing icterus, cyanosis, and hæmoglobinuria.

A congenital heart-disease, though accompanied by cyanosis, would not exhibit the other symptoms of infectious hæmoglobinæmia.

Prognosis; Course.—The prognosis of the disease is exceedingly unfavorable. Only five instances of recovery have been reported, one in the practice of Winckel, two in that of Bigelow, and two in that of Pollack. The duration is somewhat variable, but in all cases short. Pollack's cases died on the second or third day of the disease. The average duration of it in Bigelow's cases was five days, the longest being eleven days, and the shortest sixteen hours. In Winckel's cases the average was thirty-two hours, the shortest time being nine hours and the longest four and a half days. Sandner's patient lived only six hours, Strelitz's two days, Herz's one to two days. Most of Winckel's patients died in convulsions and collapse, and this appears to have been true of most of the cases of other observers.

Treatment.—The course of the disease is so rapid and pernicious that efficient treatment is usually out of the question. The chief dependence must be placed on nourishment, tonics, and stimulants. As the child will not nurse, milk must be expressed from the breast and given in small quantities. The patients of Bigelow's who recovered were given tincture of the chloride of iron and wine. Temporary benefit was obtained in Hirst's case by the use of inhalations of oxygen.

PART III.

SURGERY.

MINOR SURGERY AND EMERGENCIES IN CHILDREN.

By CHARLES W. DULLES, M.D.

MINOR SURGERY.

The limits of this work make it undesirable to attempt to go in detail over the whole ground of minor surgery in the present article, and it will therefore be restricted to the consideration of the points likely to arise in the practice of every practitioner. These will be discussed in as general a way as possible, leaving to each reader to fill up the outline from his own experience or reading in treatises specially devoted to the subject.

At the risk of repeating what may be said in other parts of this work, a few general remarks in regard to the management of children who require surgical care may not be out of place here. The treatment of patients of this class calls for great skill and judgment in matters which are usually much more simple in the case of adults, and the conditions presented often demand peculiar address in meeting them.

Usually one of the first things to be done when called to attend a child in an emergency is to secure the confidence of its parents or care-takers. This can generally be accomplished by maintaining a thoroughly composed bearing. There must be no evidence of excitement on the part of the surgeon; and, while his mind misses nothing of the gravity of a serious case, his actions must be calm and steady and he must never make too much of trifling injuries. Very often his first investigations will convince him that no great danger threatens; and, as soon as he feels fairly sure of this, he should communicate his opinion to those who anxiously await it. In doing this it is generally easy to make any reserves which prudence may dictate, without lessening the effect of his comforting assurances.

At the outset it is also necessary sometimes to quiet the commotion caused by an accident and to restrain the zeal of unwise helpers. This calls for a discretion which may be recommended but cannot well be taught. It is much helped by an avoidance by the surgeon of everything like fuss or display and of too great haste to do his work. By-standers whose feelings require that they should do something may be quietly sent to bring towels or water, or given any commission which will occupy them, and those of steadiest nerves can be kept in the room.

Another important first step in the care of children who have met with an accident is to secure their own trust. This is usually not so hard as it sometimes seems. A gentle and composed manner in the surgeon is usually appreciated by even the youngest children, and a few kindly or comforting words will often work wonders with them. Of course there should be no display, before a young patient, of excessive zeal or of surgical instruments. Then there is an art in securing an examination which comes only with practice, and is generally best understood by those who have children of their own. If a child has not been taught to dread "the doctor," it will usually submit to being taken in his arms and soon "make friends" with him.

When this point is reached, the next step is to make a physical examination, in order to ascertain the exact nature of the trouble or injury present. This may be a comparatively easy task or a very hard one. The account gathered beforehand may give the surgeon a good idea of what he will find, or it may leave much to be learned by personal investigation. In any case it is of the utmost importance that the surgeon shall not be led, by the history of the case or by its most striking features, to overlook any condition requiring attention. I happen to know of a case in which an infant was treated almost to its death for an intestinal disorder, without detection of a fracture of the humerus, the pain of which probably caused the fatal result, and of another case in which a fracture of the femur in a very young infant escaped the detection of a physician for several weeks.

It is not always necessary to examine every part and organ of a child's body; but a surgeon should never forget that he may have much more to deal with than what he is asked to treat, and he should never neglect to examine or inquire about the condition of a child's nervous, respiratory, circulatory, and digestive apparatus, or to ascertain if there is present any gross lesion which has not attracted the attention of others. I think it is of importance also to pass in review, at least mentally, the various natural passages or openings on the surface of the body,—the conjunctival surfaces, the nose, the ears, the mouth (with the teeth and tongue), the anus, and the cavities of the genitalia. In regard to these matters less thoroughness is required in some cases and more in others; but the surgeon should never be hasty or careless, and he should always decide for himself what sort of investigation is expedient, and what is not.

After making an examination of his patient, the surgeon determines what is to be done, according to the special conditions present. In some cases operative procedures are required, in others none. In many cases pain demands special consideration. In these I think the surgeon should bear in mind the fact that the relief of pain is of much greater importance to children than it is to adults, and use opium, in some form, without timidity. Six or seven hours of sleep will often transform the appearance of a child who has suffered much pain, and produce a wonderful improvement in its condition.

To produce surgical anæsthesia in children, I think chloroform the best agent, if administered with prudence; although ether is usually a satisfactory agent, while it is regarded as safer than chloroform by many medical men.

In concluding these preliminary remarks, I would call attention to the very great importance of observing—and, if necessary, treating—the general condition of every surgical case as long as it is under the surgeon's care. One who would be a skilful surgeon must be a good general diagnostician and therapeutist, and he must know when to call the materia medica to the assistance of his surgical armamentarium. This is as true in those conditions which I have been asked to discuss as in the graver ones assigned to other contributors to these volumes.

DRESSING-MATERIALS.

It has not been long since articles treating of surgical dressings were filled with descriptions of a large variety of materials and many methods of arranging them; but the practice of surgery in the present day calls for few dressings, and these are applied in very simple ways.

Wounds may be rendered aseptic by washing with boiled water and sometimes by the application of solutions of corrosive sublimate (one to two thousand) or carbolic acid (one to one hundred), after which they may be strewn with powdered iodoform or naphthalin or bismuth, while pulverized white sugar or powdered sulphur may be used for the same purpose. After this they are covered with an aseptic layer of gauze or absorbent cotton or fine jute, over which is placed an impervious layer of rubber tissue or waxed paper, the whole being retained by a suitable bandage.

Such dressings often remain in place until a wound is healed, or until some rare accident demands their removal for inspection of the wound.

Antiseptic gauze is composed of cheese-cloth thoroughly boiled and impregnated with corrosive sublimate or iodoform, and can be procured at a very moderate price from any instrument-maker, or can be made without much trouble.

Lint is now used chiefly in making wet applications or to hold ointments, when its bulk, softness, and uniform texture are of advantage.

Absorbent cotton, *jute*, and *fine carded wool* are used to make and maintain uniform and equable pressure: they are usually applied over the dressing of gauze, or over its protecting rubber tissue or waxed paper.

Bandages are made of soft muslin or flannel, and, as a rule, they are more comfortable and easier to apply if of cheap and rather open-meshed material.

Splints are made of thin metal, very light wood, binder's board, or felt fabric. Many useful splints are obtainable from the instrument-maker; but there are few cases in which a perfectly suitable splint cannot be made out of thin strips of pine wood, or pasteboard obtained from boxes or, if necessary, from large books. The function of splints is often overestimated, and a little ingenuity will usually secure satisfactory means of fixation and support anywhere.

Adhesive plaster, as now in use, is made of resin plaster or rubber plaster spread upon strong twilled cotton cloth. The latter is often preferable to the former because it does not require heat for its application; but it is less desirable when the plaster must remain long on the skin, as it is likely to give rise to the formation of an acneform or eczematous eruption. In removing adhesive plaster dressings, it is especially important in the case of children to remember that it is not always necessary to remove all that has been used, and that it may suffice to cut through the strips over or near the wound, leaving the sides undisturbed, and placing any new strips that may be needed over and upon the old ones. Much irritation may be saved a patient in this way. It is also well to remember that when a strap crossing a wound is to be removed, the proper plan is to loosen it from both ends and draw on them towards the wound, and *never away from it.* Another little point of importance is that the removal of an adhesive strip is less painful, as a rule, if it is done quickly and with a steady pull, instead of slowly and by jerks; also, that to pull in the direction of the hairs causes less pain than to pull against it.

THE CLEANSING OF WOUNDS.

It is a cardinal point of modern surgery that no wound shall be dressed until it is perfectly clean. This rule may sometimes be relaxed in cases in which nature has already covered a wound with a healthy scab, and sometimes after machinery accidents, when the grime which accompanies them is very tenacious. But in most cases, and especially in the wounds of children, a preliminary cleansing is imperative. This can often be effected by touching or pressing the part with dry absorbent cotton, or cotton which has been moistened and then squeezed nearly dry, or lint, or either of these very slightly moistened; actual lavement is by no means always necessary. When actual washing is required, there should be two vessels, one to contain the water and another to receive it as it flows from the part. The water may be conveyed through a small hose, or may come directly from a spigot, or it may be allowed to fall in a steady stream from a sponge or a mass of cotton, squeezed in the hand, the size of the stream being regulated by the compression, and its force by the height at which the hand is held.

THE CONTROL OF HEMORRHAGE.

An important part of the preparation of a wound for dressing is the control of hemorrhage,—not the hemorrhage from large vessels, but that from small ones, such as are usually encountered in the surgery of general practitioners and with children.

In almost all bleeding from small vessels, the pressure of a well-applied dressing, especially if elevation be also employed, will do all that is needed in the way of controlling hemorrhage. Such a dressing may be made of dry lint, or lint moistened and squeezed nearly dry, bound on with moderate firmness,—actual tightness is not called for; and often one will have in a little while an imitation of nature's favorite method of healing, by the formation of a scab made up of the dried blood and the tissue of the dressing. The essentials for controlling moderate hemorrhage are dry or nearly dry dressings and moderate compression. Pressure alone is sufficient to control the bleeding from scalp-wounds, which are sometimes spoken of as if they were troublesome to deal with. A compress and bandage will occlude any vessel in the scalp, and almost anywhere else; and, if an unruly patient is likely to pull a bandage off, a pin may be thrust under the vessel and brought out again beyond it, so as to hold it as long as any one could wish. If still greater security be desired, it can be had by adding a "figure-of-eight" to this pin.

DRESSING OF WOUNDS.

Nature's method of protecting wounds is by the process of scabbing; and when we reflect upon the successful way in which this operates in the lower animals, and often in man too, we may wonder that it should be almost a matter of routine to remove scabs in surgical practice. It may gratify our curiosity, it may even aid our study at times, but it is often of no advantage to the patient, to remove from a disfigured face or a cut head the crusts which are nature's reliable antiseptic dressings. It is often well to leave such crusts undisturbed, and, if they are objectionable in an æsthetic sense, simply to cover them with something better-looking. An artificial scab made with lint, or tarlatan, or thin muslin, and collodion, forms one of the best dressings which have ever been devised for simple incised and not a few lacerated wounds. Many cut heads and simple incised wounds, even after the removal of tumors, go to a prompt and uninterrupted healing under the first dressing of this sort. Efficient scabs may be formed by allowing lint to become saturated with the oozing of a wound exposed to the air. Dry powdered borax, or boric acid, or iodoform, may also be used to promote the formation of a crust. In all these cases, however, it is important to watch lest the crust bind down offensive discharges, as any scab may do: when this happens, the crust must, of course, be removed, and the wound cleaned.

In the case of strumous ulcers and the weak granulations of large burns, the happiest results may sometimes be obtained by setting aside ordinary dressings, and applying a powder in this way. In these latter cases, exposure of the granulating surface to the air until the serous film covering them has coagulated and formed a species of skin over them is at times of great service.

Lead-water and laudanum is but little better than cold water, so far as my experience would indicate, although it is suited to cases in which there is much heat and pain. This dressing ought never to be covered up, as it very often is, with impervious coverings. Pure laudanum is often a very soothing application.

Dilute alcohol is a refreshing dressing, if it be allowed to evaporate and be removed at the first sign of pain.

The ointments in use in simple surgery are very numerous. The best are fresh cold cream, vaseline, oxide-of-zinc ointment, and equal parts of this and carbolic-acid ointment. The latter are stimulating in their action. A piece of lint or muslin should be spread with the ointment and trimmed down to the exact size of the sore. If spread on the adjacent skin, it will often after a while set up an artificial eczema, very annoying to the patient.

The use of poultices is often overdone. Poultices are of service when it is desired to increase vascular activity in low grades of inflammation, with depressed circulation, and when it is desired to promote or increase pus-formation. But they do their work in a short time, and their prolonged use may bring about a condition in which nature seems unable to get beyond the production of a very feeble and unhealthy sort of tissue. Kept hot and frequently changed, so as to get away filthy discharges or sloughing tissue, for a few days they are invaluable; but allowed to cool, left on long at a time, and continued for many days, they may do great harm. When a slough is to come away, as after cauterization or the opening of a felon or carbuncle, nothing equals poultices for comfort and effectiveness. But, even in these cases, one should give them up as soon as the slough is away, and treat the wound as a simple ulcer.

There are no cases which so much enforce this conviction as those of deep inflammations of the hand and foot,—felons and palmar and plantar abscesses. I have seen many cases which have illustrated the advantages and disadvantages of the use of poultices in the most impressive manner. Hands affected with deep palmar inflammation are sometimes almost sacrificed to the persistent use of the poultice; and they would turn back to recovery if the poultices were laid aside and nature given a chance to do what she could without them. Felons well opened and then too long poulticed may keep unhealed for a long time, the tissues of the finger becoming boggy and of low vitality.

A felon should be opened deeply whenever there is pus actually present, —never before, for then it can be aborted; then bleeding should be encouraged by a good soaking in very hot water; then a poultice should be used for *one day only*, soaking frequently in water as hot as can be borne. After this the part may be dressed with pure laudanum, or lead-water and laudanum, or a simple ointment, unless there is obviously a slough forming; and the patient may usually be dismissed in a few days. When a felon has gone on to destruction of the vitality of bone or tendon, poultices may be used longer; but one should be always on the lookout for the time when they can be thrown aside.

The best treatment of palmar and plantar abscess, or rather of deep inflammations of the hand and foot, cannot be stated in a few words; but alas for the patient whose doctor is too timid to use the knife and too assured of the saving grace of the poultice! Too little of the one and too much of the other is a sad combination.

The pressure which can be secured with adhesive straps is useful in a number of inflammatory conditions. The application of narrow straps will furnish great relief in the case of boils and carbuncles, and I have had cases of paronychia which resisted assiduous treatment for a long while, but in which immediate relief and rapid recovery followed the application of a circular dressing of adhesive plaster round the end of the finger.

Collodion is another agent which may do good service in minor surgery. Many wounds can be easily and effectively coaptated by drawing the edges together, laying over them a strip of tarlatan or other bandage, and saturating it with collodion. It should be remembered, however, if one is dealing with children, that collodion applied to a raw surface is very painful for a while. In applying dressings to the face a bandage may often be entirely dispensed with by using collodion in this way, or by placing against a small wound or ulcer or fistulous opening a little absorbent cotton and gluing its edges down with the collodion; and a neat, soft, absorbent, but impermeable dressing will be made.

A mistake is sometimes made in bandaging too tightly. There is another error, much commoner, and that is bandaging too heavily. Children sometimes come to dispensaries with a member firmly bound to a splint, with the laudable object of preventing injurious mobility, but loaded down with successive layers of bandage, till the heat has set up an active inflammation, with the customary accompaniments of pain and swelling, which subside when the lightest possible splint is used and the thinnest possible bandage.

Sometimes it is desired to apply water after a bandage has been put on. In such cases, of course, the bandage should be thin and open-meshed, and put on as loosely as is consistent with safety. For this purpose the cheap unbleached muslins are far better than the fine ones furnished by the instrument-makers, and cheese-cloth may be better still. Water can also be insinuated under a bandage, if the member has first been wrapped in a layer of absorbent cotton or lint.

The placing of cotton under a bandage has other important uses than to facilitate the application of water,—*e.g.*, to exert uniform pressure, to prevent swelling, to promote absorption of effusions. One who has not tried it systematically would hardly believe what this sort of compression will accomplish; and it might be set down as a rule, that all contusions of joints, and most inflammatory swellings, should be subjected to the equable compression and gentle warmth of dry cotton and a pretty firm bandage. This method is better than the traditional lead-water and laudanum.

An important point in regard to splints, and worthy of particular mention, is their weight. A splint should be no heavier or thicker than is absolutely necessary. The lighter the better, is a good principle. Let light pasteboard be used when possible, or the very thinnest wood. Nor need the weight and thickness be increased by padding. This is especially true in regard to splints for the arm, where wooden splints are oftenest used. In most cases in which splints are used it is sufficient to wrap a thin wooden splint in waxed paper, to make it perfectly smooth and keep it clean, and to interpose between it and the arm a double strip of lint. These may be fastened in place on the arm with three or four strips of adhesive plaster, avoiding the seat of fracture or other injury, and covering all with a light bandage. Then the parts can be examined at any time by simply removing the bandage, without taking off the splint or disturbing the seat of injury. Cotton may be placed where the member does not touch the splint, and bony prominences must not be pressed too hard against it.

The best splint for the forearm and hand is, I think, the posterior straight splint. Any one who studies a forearm will see that when the hand and fingers are extended, the dorsal surface is almost an accurate plane, while the ventral surface is very uneven. A straight splint fits the back of the arm and hand accurately, secures perfect fixation, and permits use of the fingers so as to avoid the risk of stiffening better than any other. The posterior splint has decided advantages in the way of lightness and the facility it affords for examining the seat of injury without disturbing it. The Bond's splint, on the other hand, as frequently applied, is heavy, hot, more or less painful, and troublesome to remove for subsequent examination.

It ought to be an *invariable* custom, with those rare exceptions in which for the purpose of drainage it must be reversed, to have a sling so regulated that it will *support the hand at a higher level than the elbow.* A neglect of this very simple and, I believe, very important rule is sometimes followed by great pain and swelling of the hand and by a degree of discomfort which would be incredible to one who had not investigated the matter. Further, a sling should be broad enough to support more than a narrow strip of the arm, or one will be apt to find its position marked by a furrow dividing two swollen parts of the arm, in a manner which is not neat, and which suggests possible injury or interference with the most rapid recovery. Another point about slings concerns the length of time they should be used. Here our routine is sometimes too rigid. It cannot be stated exactly how long a sling may be useful; but I have often found it of advantage to let an arm be taken out and allowed to swing at the side, at least occasionally, long before the splint could be dispensed with.

In the treatment of children for minor injuries it is well to bear in mind that their tissues usually heal kindly and promptly, and that there is such a thing as making too much fuss over them and investigating them too frequently. There are probably cases in which a few strips of adhesive plaster and a neat bandage would do better than a formal dressing and a splint. On the other hand, there are some injuries which in children require a splint, although in adults none is needed.

In conclusion, it may be said that in all the minor surgery and treatment of accidents in children the surgeon should aim to exercise keenness without fuss, thoroughness without severity, gentleness without weakness, patience without indifference, and foresight without apprehension. There are no patients who demand more good qualities of head and heart, and none who make better returns for their exercise.

EMERGENCIES.

The accidents and emergencies to which children are liable are different from those of adults, in that there are some to which the former are more exposed than the latter, and some to which children are not liable while adults are. The most usual emergencies in children we will consider, taking those which are more or less surgical in their nature and omitting those which are purely medical.

OBSTRUCTIONS TO RESPIRATION.

Drowning.—In cases of drowning, if natural breathing has ceased, the first thing to be done is to free the body from any clothing which binds the neck, chest, or waist, and to turn it over upon the face for a moment, thrusting a finger into the mouth and sweeping it round, to bring away anything that may have got in or accumulated there. Then the body should be laid out flat on the back, with something a few inches high under the shoulders, so as to cause the neck to be stretched out and the head to be carried well back. The tongue should now be drawn forward out of the mouth and held by an assistant, or, if there be no one to do this, a pencil or small stick may be thrust across the mouth on top of the tongue and back of the last teeth, to keep the mouth open and the tongue out of the throat. A very good way to get the base of the tongue clear of the windpipe is to carry the head well back from the chest and to press the angles of the jaw forward with both thumbs applied just behind the rami of the lower jaw-bone.

To secure artificial respiration the operator should place himself on his knees behind the patient's head, seize both arms near the elbows and sweep them round horizontally, away from the body and over the head, till they meet above it, when a good, strong pull must be made upon them and kept up for one or two seconds. This effects an inspiration. (Fig. 1.) The second manœuvre consists in returning the arms to the anterior surface of the chest, and making strong pressure against the lower ribs, so as to drive the air out of the chest and effect an act of expiration. This need occupy but a second of time. (Fig. 2.) Another plan is to hook the fingers under the ribs and draw them up firmly, though gently, and then release them.

Fig. 1.

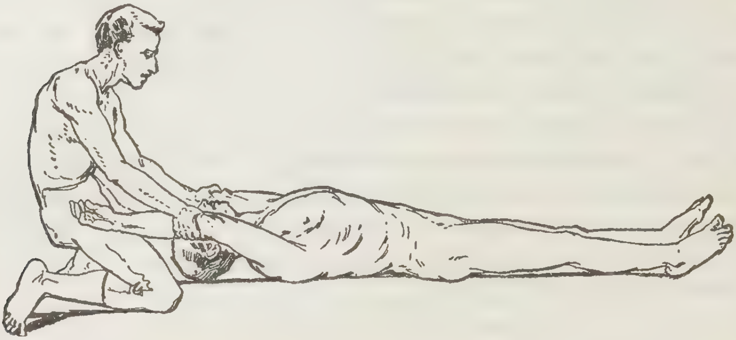

Fig. 2.

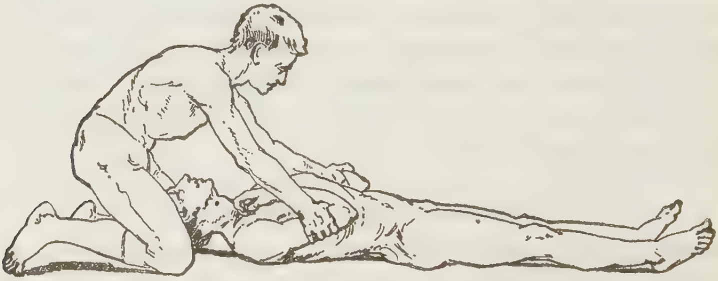

If either of these plans is regularly carried out, it will make about twenty complete acts of respiration in a minute. It should be kept up for a long time, and not abandoned until recovery of natural respiration or until the heart has ceased to beat. The cessation of the pulse at the wrists must not be taken for a sign of death. Often life is present when even an acute ear cannot detect the sound of the heart. Deep pressure with the finger-ends just below the lower end of the sternum may sometimes reveal pulsation in the aorta when it cannot be found anywhere else.

Wet clothing should be removed from a drowned person as soon as possible. This can always be done without interrupting the artificial respiration or exposing the person. Something may be laid over the body and the wet clothes loosened under it and drawn down over the feet. Then the body may be quickly slipped on to something dry, and covered with some other fabric, if the first has become wet, while this, in its turn, is pulled away from underneath.

Warmth is to be secured by any means which ingenuity may suggest,—hot bottles, or plates, or bricks, or stones, or even boards that have lain in the summer sun. At the sea-shore there is plenty of hot sand, and often plenty of baking bathing-costumes. The body and limbs may be gently, but constantly, rubbed towards the heart, to help the blood in its labored circulation. None of these things need interfere with the efforts to secure respiration, which must be uninterrupted.

Some stimulant is to be given as soon as it can be swallowed. Half-teaspoonful doses of whiskey or brandy, in two teaspoonfuls of hot water, may be given every ten minutes, till an ounce has been taken.

As natural respiration begins to be attempted, it should be aided as much as possible by timing the artificial to it. It may be stimulated by carefully applying smelling-salts, or hartshorn, to the nose, by slapping the skin lightly but smartly, or by dashing hot water upon the chest. Where it is available, there is no stimulus to respiration better than that of a good faradic battery used so as to cause a reflex sobbing, or deep breathing, by the pain it causes. Little by little natural breathing will take the place of the artificial; but it must not be left unwatched for some time.

Nothing but danger from cold, or pressing necessity, should prompt the removal from one place to another of a child who is being resuscitated, before this has been thoroughly accomplished. If removal cannot be avoided, it must be effected with great care. After resuscitation the child should be put in a warm bed, being carried carefully, with the head low, and a watch should be kept to see that the breathing does not suddenly stop.

Where natural breathing has not ceased, all the steps just described should be carried out, with the exception of artificial respiration. But this should be had recourse to upon the first evidence that natural respiration is failing.

Strangulation by hanging, or by anything which compresses the trachea from the outside, is to be treated by re-establishing the respiration in the same way as for drowning. The obstruction is, of course, to be removed, and natural respiration stimulated or artificial respiration employed. Hanging is not an unheard-of accident with children, as they may hang themselves accidentally, and a child has been known to hang a younger one in imitation of what it had heard described by its parents.

Suffocation with noxious gases or vapors calls for instant removal to the fresh air and for the establishment of natural respiration, or of artificial until the natural is re-established, as described in speaking of drowning.

In strangulation caused by a foreign body in the throat, œsophagus, or trachea, it is not always easy to tell which of these passages is clogged, but usually there is an active irritation, with coughing, when a foreign body lodges in the larynx or trachea, while swallowing can be done quite readily. On the other hand, when the œsophagus is stopped it is usually impossible to swallow, and there is little or no tendency to cough, no matter how much the breathing may be interfered with. Foreign bodies in the fauces or larynx are not so hard to discover.

If a foreign body be within reach of the fingers, it may often be easily removed. If not, a pair of forceps may be used, or, in a pinch, a pair of blunt-pointed scissors. Or a hair-pin may be straightened out and one end bent round so as to make a loop, and this used to dislodge the foreign body; or the handle of one blade of a pair of scissors may be used in the same way. It has been stated that for foreign bodies in the throat, such as pieces of meat, etc., a simple mode of relief is to blow forcibly into the ear. This sometimes excites powerful reflex action, during which the foreign body is expelled. Such a plan is so easy of execution that it is certainly worth trying.

Children not infrequently get buttons, coins, or marbles in their throats. These may often be pulled out or expelled by vomiting induced by titillation of the fauces, or by an ordinary emetic or a hypodermic injection of one-sixth of a grain of apomorphine. Holding the body up by the legs, with the head hanging down, may sometimes aid other efforts to get rid of such things. Attempts to push the foreign body down may prove successful.

If foreign bodies get into the larynx or trachea, a moderate blow on the back with the open hand, or a quick strong squeeze of the chest, sometimes aids the coughing act; and inverting the body may assist in dislodging the foreign body if it be not too tightly wedged in. If this does not succeed, they may be removed with forceps, or laryngotomy or tracheotomy may be required.

When coins, marbles, slate-pencils, or nails are swallowed by children, it is usually a mistake to give an emetic or a purgative. The proper plan is to let the bowels alone and to give plenty of good solid food, especially vegetables, so that the foreign body may be surrounded with the waste and carried out of the body without injuring the walls of the intestines.

FOREIGN BODIES IN THE EYE, NOSE, AND EAR.

Foreign Bodies in the Eye.—Small substances, like cinders, dust, or small chips of stone or metal, can often be removed from the eye by very simple means. Sometimes the flow of tears washes them out. At other times catching the upper lid by the lashes and pulling it away from the eyeball and down over the lower lid, then letting it go so that as it recedes its under surface is swept by the edge of the lower lid, will clear it out. If this does not prove successful, a loop made of a horse-hair or of a long human hair can be passed under the lid and swept from the outer side towards the nose and drawn down. This may serve the purpose. If it does not, the upper and lower lids must be everted and examined with a good light and the aid of a lens if necessary.

The eyeball must also be examined and any foreign substance removed.

One must be on his guard against the sensation which is sometimes left after a foreign body has been removed from the eye. But a most careful search should be made before this is taken to be a self-deception.

After removing a foreign body from the eye, the irritation may be sufficient to demand cool, wet applications, or even anodynes. Nothing is better than a thin mucilage of pure, clean gum-arabic poured freely in the eye; or a drop of a four-per-cent. solution of cocaine, or of a one-per-cent. solution of atropine, may be applied to the eye. A bandage loosely applied often does much good.

When lime gets in the eye, the eye should be deluged with water, and a little vinegar or lemon-juice and water (a teaspoonful of vinegar or lemon-juice to a teacupful of water) poured over the eyeball.

Foreign Bodies in the Nose.—Children sometimes place, or have placed, in their noses small bodies, such as marbles, buttons, peas, beans, or small grains. To get rid of them the nose should be blown hard, or sneezing may be excited by tickling the nose or giving snuff, or the child may be told to take a full breath and then be given a smart blow on the back. Some one of these plans may dislodge the foreign body. If it does not, the affected nostril may be closed while the other is blown into, through a rubber tube, and on suddenly releasing the closure of the side occupied by the foreign body it may be driven out. If none of these methods succeed, instrumental extraction will be required.

Foreign Bodies in the Ear.—The removal of foreign bodies from the ear is so delicate an operation that, when possible, a specialist should be asked to do it.

If the body be a metal or mineral one, the ear may be syringed out thoroughly. When instruments are used, it must be remembered that great damage may be done by the least roughness. The use of the forehead mirror is almost always indispensable, and care must be taken not to mistake the glistening of the membrana tympani for a foreign body.

If live insects get into the ear, oil or glycerin or salt-and-water should be poured in. Or a plug of cotton soaked in a strong solution of salt and vinegar may be placed in the ear and the head turned over on that side. A method which has sometimes been successful is to turn the ear to a bright light, so as to tempt the insect to back out.

LOSS OF CONSCIOUSNESS, AND CONVULSIONS.

The causes of unconsciousness may be classified as disorders of the circulation, disorders of the brain, poisoning, and intoxication. The latter, of course, is very rare in children.

Unconsciousness due to disorder of the circulation is familiarly illustrated in fainting. It is marked by paleness of the face, and usually by coldness of the extremities.

Unconsciousness due to disorder of the brain may depend upon disease or injury. Disease of the brain is recognizable from its gradual approach. Injuries of the brain are usually accompanied by external signs, such as dirt, swelling, bruises, or cuts, which show that violence has been inflicted, or they occur under circumstances which make a suspicion of violence reasonable. In apoplexies some of the external evidences might prove misleading, but besides these there are often found an unequal dilatation of the pupils and paralysis on one side of the face and body. In the unconsciousness of epileptic convulsions there are usually frothing, biting of the tongue or lips, and the peculiar cry before unconsciousness sets in.

Unconsciousness due to poison may be caused by a poison generated within the body, as in serious kidney-disease. In such cases there are usually convulsions as well as unconsciousness, and often a dropsical appearance about the eyes and legs, very profound stupor, and a smell like that of urine about the person affected.

The cause of poisoning by gases is generally easy to detect. In insensibility due to opium or chloral the pupils are strongly and rigidly contracted, the very opposite of what is seen in drunkenness.

Unconsciousness due to intoxication is marked by many signs of other insensibilities, but it has these peculiarities: the face is usually flushed, the body relaxed everywhere, the person capable of being roused by loud cries, the pupils dilated evenly, and a distinct odor of liquor may often be discovered.

In determining the cause of unconsciousness the following plan may be adopted:

1. *Examine the head.* If there is a cut or a bruise, it is to be suspected that there is a brain-injury.

2. *Examine the pupils.* If they are permanently contracted and do not dilate when the eyes are shaded, it is probably a case of brain-disease or opium-poisoning. If one pupil is contracted and the other dilated, it is a case of injury or disease of the brain.

3. *Examine the face.* If it is drawn and wrinkled on one side and smooth on the other, the case is one of apoplexy, or embolism in the brain, or pressure upon some part of the brain.

4. *Examine the mouth.* If it is frothy and if the tongue or the lip is bitten, it is probably a case of epilepsy. Of course it will be borne in mind that the tongue may be bitten accidentally by being caught between the teeth in a fall.

5. *Examine the arms and legs.* If one is rigid and one relaxed, or if one moves when pinched and the other does not, it is hemiplegia or hysterics. If it be the latter, the person affected will usually resist any attempt that may be made to open the eyelids; and when the eyelids are forcibly opened the eyeballs will usually be found persistently rolled up, which may be regarded as an almost infallible evidence of hysterics. At the same time, close watching will generally lead to the discovery of some sign that the affected person is listening to what is being said about him or her.

6. *Examine the temperature of the skin.* If the skin be burning hot and dry, sunstroke or heatstroke may be suspected.

The treatment suitable for all cases in which there is doubt as to the cause of unconsciousness is to secure quiet and rest, the body being laid upon the back, with the head a little raised. If there be great paleness and a cold surface, with slow, sighing breathing,—the signs of prostration,—smelling-salts or hartshorn may be held under the nose, hot tea or coffee given, and heat applied to the body. If there be great heat of the surface, cold may be applied to the body and head, and cold drinks given.

Fainting.—A fainting person must be laid out flat at once, so that the heart may not have to work against the force of gravitation in sending blood to the brain. Sprinkling water upon the face and holding smelling-salts to the nose tend to excite the nerves of sensation and rouse the brain and heart to renewed activity. Nothing else is usually necessary; though if a person is very slow in coming to, it may be well to apply heat in the form of a mild mustard plaster or hot moist cloths to the pit of the stomach.

Hysterics are best treated by the exercise of calmness and patience, sometimes by taking no notice of the attack, or by leaving the sufferer in a room alone. Heroic measures, like dashing water into the face, are not to be generally recommended. Good is sometimes done by giving valerian or Hoffmann's anodyne.

Epileptic fits are to be treated very much like fainting-fits, because in them also the brain is temporarily bloodless. At the same time, any movements calculated to injure the person must be controlled. There is no use in struggling against such as will do no injury; they had better be simply regulated, and no attempt made to prevent them entirely; but a piece of folded cloth or a piece of soft wood may be—if it can be—thrust between the teeth, to prevent the usual biting of the tongue. When the height of the convulsion is passed, rest, quiet, and perhaps a moderate stimulation may be secured. Here again the flat position of the body must be maintained.

Convulsions of children and infants are generally (in the absence of brain- or kidney-disease) due to some irritation of the digestive apparatus or to teething. They are usually preceded by some other evidence of irritation, such as restlessness and fretfulness. The spasms may affect the whole body at once, or only a half, or only one limb at a time. The eyeballs sometimes roll about or squint, or, they are turned far up, so that only the lower part of them can be seen.

When convulsions occur, the child should have cold applied to the head and heat to the body. It often seems to do good to place it in a tub of hot water to which some mustard has been added. A large injection of hot soapsuds should also be given, to clear the bowels out, and, if possible, an emetic, in the hope of removing any cause of trouble from the stomach. Irrigation of the colon with moderately cool water, as taught by Monti, of Vienna, is sometimes of the greatest service in convulsions of children. For the production of vomiting, one-sixth of a grain of apomorphine may be given hypodermically. In some cases of convulsion the administration of chloroform, or an enema containing five grains each of chloral and bromide of potassium or of sodium, will bring the spasms to an end.

Apoplexy.—For this condition, which is very rare but not unknown in children, rest and cold to the head constitute the best treatment. The bowels should be emptied, if possible, with an injection of hot soapsuds, and a purgative given by the mouth as soon as it can be swallowed.

INJURIES TO THE BRAIN.

Concussion of the brain may be caused by blows or falls on the head, or even by falls upon the feet or the buttocks. In such cases there is sickness, sometimes fainting, with paleness and depression. There is also usually confusion of ideas, and the sufferer cannot talk continuously and coherently. There may even be unconsciousness.

The proper treatment for this condition is rest in bed, quiet, and plenty of fresh air. If the skin becomes cold and clammy, heat should be applied to the body and limbs. No whiskey or brandy should be given.

Compression of the brain is marked by loss of consciousness, sometimes paralysis, sometimes twitching of the muscles, or even convulsions, and usually heavy snoring breathing, with wide dilatation of one or both pupils. The treatment is the same as for apoplexy.

EFFECTS OF HEAT.

Burns or scalds are usually dangerous in proportion to their extent and depth. Those which involve as much as half the surface of the skin are almost necessarily fatal.

After an extensive burn or scald, so much of the clothing as has to be removed must be clipped away, so as not to burst blisters that have formed. These may be punctured at one edge and their contents allowed to run out, and the elevated cuticle to fall down upon the deeper layer. Then a dressing of pure sweet oil, castor oil, or vaseline is to be applied on strips of soft old linen, and disturbed as little as possible afterwards. Iodoform is a very soothing application to burns, either in powder or in an ointment; although its prolonged use has a tendency to promote or prolong suppuration. Carron oil is also an excellent application, and stimulants or anodynes may be given as required. In case of a severe and extensive burn, the entire body may be immersed in a bath, to be kept at a temperature of 100° F.

Slight burns or scalds are best treated by applying a cloth soaked in a strong solution of baking-soda—the bicarbonate—in the proportion of a heaping tablespoonful in a teacupful of water, or it may be powdered on without using any water. Carron oil is a good application for such burns. So is the white of egg. In an emergency damp earth may be used, or white-lead paint. Anything may be used which will prevent friction and exclude the air; but nothing should be used which will stick in cakes and prevent after-examination or make this very painful. For this reason flour and cotton batting, though often recommended, had better not be used. For small burns, simple cool water is better in every way than these. Indeed, for any but the most extensive burns it is one of the best remedies: an arm or a leg can be immersed in it and left there a long while with great advantage.

Burns with acids must be deluged with water and then treated like other burns.

Burns with caustic alkalies, such as soap-lye, should be treated with an application of vinegar, followed by applications of oil.

Burns with hot pitch.—After such burns the pitch often sticks. In such a case it ought not to be removed immediately unless in excessive amount.

Sunburn, and the burns caused by external applications, like mustard, may be treated very successfully with bicarbonate of sodium. This may also be mixed in equal parts with vaseline, cosmoline, or lard from which the salt has been boiled out, and used as an ointment.

Sunstroke, or more properly **heatstroke**, is not usually due to the direct rays of the sun, but rather to a prolonged elevation of the bodily temperature, especially in confined places. When it takes place in the open air it is apt to be on oppressive, heavy, or murky days. It is generally preceded for some time by pain in the head and a sense of oppression. The attack, however, culminates in loss of consciousness, with heavy, labored breathing, and an intense burning, dry heat of the skin, while the bladder and bowels are often involuntarily evacuated. The absence of perspiration in the presence of so great heat is one of the most characteristic symptoms of heatstroke.

The treatment consists in first lowering the temperature. As much of the clothing as practicable must be removed, and the patient should be transported to a cool and airy place if possible. Cold must then be applied to the head and body, and ice may be rubbed over the chest and placed in the armpits. Pouring or dashing cold water over the body is not to be advised, as it conveys a needless shock to the system; but there is nothing better than to place the body in a cold bath, or to wrap it in sheets kept wet and cold by renewed applications of cold water or ice. The temperature of the body must be watched, as there is some risk of pushing its reduction too far. When the temperature has been brought down to 100° F. or consciousness has returned, the cold may be discontinued, to be renewed only if the surface becomes again very hot.

Heat-Exhaustion.—This is a condition of great depression of the system due to the action of heat, and, occurring in hot weather, it might be confounded with sunstroke or heatstroke. But in heat-exhaustion, instead of a hot, dry skin, there is a cold, moist one. This calls for rest, fresh air, and a cool apartment, but for no application of cold to the surface. Small doses of brandy or whiskey thoroughly diluted may be given, and the system gradually brought back from its depression.

Lightning-Stroke.—This is marked by evidences of shock, with reduction of the force of the circulation, weak pulse, and slow, sighing breathing. It is to be treated with rest and stimulants, and warmth applied to the body.

EFFECTS OF COLD.

Freezing is best treated by gradually bringing the temperature up to that which is normal and maintaining it there. When fingers or toes are frozen or frosted, warm baths and gentle friction are to be used, afterwards covering with a thick, hot poultice. In such cases gangrene not infrequently follows the freezing. Frozen ears or noses are of less frequent occurrence, but must be treated on the same principles.

If the whole body has been exposed to extreme cold, there will follow a depression which requires the most cautious treatment. To restore its warmth is the first demand, and for this a warm bath, made gradually warmer until as hot as can be well borne, surrounding with heated blankets, or exposure before an open fire, may be used.[1] At the same time, stimulants may be given internally, such as hot tea or coffee, with the addition of small quantities of spirits.

SPRAINS.

Sprains of the fingers or of the wrist require cold and moist applications. In the latter the hand and forearm should be covered with cotton, bandaged smoothly, and laid on a straight splint and lightly secured to it with a soft bandage or broad strips of sticking-plaster. One of these should go round the hand and one or two round the forearm above the wrist,—not over it. Sprains must be treated by rest, and by heat or cold, whichever gives the most comfort.

Sprains of the ankle are not infrequently complicated with a fracture of one of the malleoli. This complication may give rise to much trouble, and requires very skilful and patient treatment. The general principle in the case of a sprained ankle is, first, to put the joint at complete rest, to allay inflammation if it arises, and afterwards to promote the absorption of inflammatory products. The foot and ankle should be covered with cotton or carded wool and a bandage carefully and smoothly applied. The use of a splint may usually be dispensed with, if the bandaging is well done. In some cases, however, a splint such as is used after tenotomy for club-foot is of great service. The dressings may remain undisturbed for days if the ankle is comfortable. If the dressings become loose from rapid diminution of the swelling, they should be removed and reapplied. When this is done, careful massage or douching with alternate streams of hot and cold water may be useful.

After the inflammatory stages—if they have not been averted—any deposits may be removed by massage, douching, and careful passive motion.

---

[1] This recommendation is contrary to popular belief, and contrary to what is taught in most text-books, as well as in books on the treatment of emergencies. But it has been proved to be correct by experiments made in Russia, where it was found that the best way to resuscitate dogs which had been frozen was to put them at once into a hot bath. Of twenty animals treated by the "gradual" method in a cold room, fourteen died; of twenty introduced at once into a warm room, eight died; of twenty placed immediately in a hot bath, *all recovered.*

WOUNDS.

Wounds may be classified as contusions, contused, lacerated, punctured, poisoned, incised, and gunshot wounds.

Contusions are best treated at first, when painful, by the application of cold wet cloths. Pure laudanum is often a very acceptable application. Later, when the pain has subsided, hot wet cloths are best, as they favor the carrying off of the blood that has escaped.

In contusions of the chest or abdomen internal organs may be injured. Evidence of this may be seen in spitting of blood, or vomiting it, or passing it from the bowels or from the bladder; or there may be great depression. In such cases complete rest must be secured, and the strength of the sufferer sustained by means of warmth applied externally and careful stimulation internally, until the nature of the injury is exactly made out and a suitable line of treatment may be adopted.

Contused Wounds.—These are cuts or tears accompanied with bruising of the tissues. They are to be treated like lacerated wounds. Unless they bleed freely, warm applications are better suited to such wounds than are cold ones.

Incised wounds, if simple and small, call only for a piece of adhesive plaster and perhaps a bandage. If large, the edges should be brought as near together as possible, and supported so by adhesive plaster or by bandages. If an entire part be cut off, as an ear, a nose, a toe, or a finger, it should be cleaned with lukewarm water, and put in its place, with sutures, bandages, and a splint. Some very remarkable cases of reunion of such parts are on record, and an attempt to save them is not to be lightly rejected.

Lacerated Wounds.—In lacerated wounds the torn parts can be placed as nearly as possible in their natural position (after removal of any foreign matters that have entered them) and covered with cool wet lint, or with lint soaked in laudanum or in alcohol and water. If the tear has been very great and the sufferer is depressed and cold, teaspoonful doses of brandy or whiskey in hot water may be administered, and lint wrung out of hot water placed over the injured parts.

Punctured wounds are made with sharp-pointed objects, like arrows, pins, needles, tacks, fish-hooks, glass, thorns, splinters, or teeth.

If a needle is run into the flesh, the surgeon should make sure whether any of it is still in the tissues or not before making an incision. In most cases this is not hard to do, but sometimes it is impossible.

Fish-hooks may be removed by a simple incision, or the string may be cut and the point of the hook pushed through the skin and the whole drawn out, as a needle would be in sewing. If it can be done, the broad part of the hook may be cut off before trying this. But this is usually not easy for the operator or the patient.

Splinters are dangerous in proportion to their size and according to the part they enter. Small splinters may be picked out with a needle. Splinters under the nails may be removed by scraping the nail as thin as possible over the splinter, then splitting it or cutting a little tongue out.

Splinters of glass must be removed by incision, and the wound treated on general principles.

Splinters in the eye should be removed with the greatest care, and, if possible, by a specialist. Afterwards the eyelid should be gently closed, both eyes covered with a layer of absorbent cotton soaked in cool water, and a bandage placed round the head, so as to keep the lids as still as possible. This bandage should not be too thick nor put on too tight, and the application should be kept cool, with ice, if need be.

Poisoned wounds are usually punctured, and result from the bites or stings of animals or insects.

The bites of venomous serpents usually demand the prompt removal of the part bitten. It may be cut out instantly. Before this the part should be encircled above the wound with a tight ligature, and, if small enough, thrust into the mouth and sucked hard, so as to extract the poison. Cauterization may be effected with anything at hand, like a knitting-needle or a nail, heated to redness. Stimulants may be administered if necessary.

The stings of tarantulas, scorpions, centipedes, etc., are to be treated with cold, and hartshorn applied to the point where the sting entered.

The stings of insects may be treated with cold wet alkaline applications: wet earth is a very good one. The application of a drop of hartshorn or some wet salt often gives great relief.

The bites of cats and rats are sometimes followed by severe inflammation. The treatment consists in cleansing the bites, and treating them as lacerated wounds.

The Bites of Dogs.—If any one be bitten by a dog in good health, only the simplest treatment will be necessary. If the dog be sick, local inflammation or severe constitutional disturbance may follow. In case of reasonable suspicion, the wound may be thoroughly cleansed and an application of hartshorn made to it, in addition to energetic sucking to extract any irritating material which may have entered it. A prolonged study and considerable experience with regard to the subject have convinced me that the general practice of cauterizing dog-bites with nitrate of silver is dangerous and should be abandoned.

Most medical men know that it is a foolish thing to kill a dog that has bitten anybody, soon after this has taken place. Such a dog should be caught and kept under the observation of a person of great carefulness, intelligence, and special information. The too speedy slaughter of a dog has robbed many a sufferer of the assurance that would have been gained by seeing it living and well, and has sent many a one to the grave, as dying of hydrophobia, who never had it, but had been bitten by a healthy and harmless animal.

SPECIAL HEMORRHAGES.

Bleeding from the nose, in children, is often nature's way of getting rid of an excess of blood; but it may be so profuse as to threaten life. If this be the case, salt-and-water or vinegar may be snuffed up the nose, injected by a fountain-syringe, or applied by pouring with the head thrown back. A strong solution of alum in very warm water is also useful; but vinegar is less disagreeable, and will seldom fail to check the bleeding. In rare cases the nares must be plugged.

In hemorrhage from the lungs the blood is bright red and generally frothy. It is rarely profuse, and yet, as it is usually coughed up and caught in a handkerchief, it seems to be so. The amount can never be safely estimated in this way. The best treatment is rest in bed with the body raised in the sitting posture, and the swallowing of lumps of ice. The application of cold to the chest, if the patient is not too weak, is of some use, and a saltspoonful of salt and a teaspoonful of vinegar may be given every fifteen minutes. Five-grain doses of gallic acid may be very serviceable.

In hemorrhage from the stomach the blood is usually very dark, looking like coffee-grounds. If it is mixed with any other contents of the stomach, its appearance may be masked. In such cases ice-water or broken ice may be swallowed, and teaspoonful doses of vinegar. Rest in bed must, and the application of cold to the stomach may, be employed, with tannic acid in five-grain doses.

Hemorrhage from the bowels may be treated with ice-water injections, the application of ice to the abdomen, and five-grain doses of tannic acid.

In severe hemorrhage, rest in bed, without a pillow, and *with the head lower than the body*, must also be secured.

POISONS.

As it is better to prevent accidents than to correct them, it is a good plan to have dangerous articles kept invariably out of reach of children, and to have any bottle containing what may be dangerous marked by a ball and chain, such as the druggists sell, or by tying a stout piece of tape round its neck. This gives warning in the dark as well as in the light.

When there is reason to believe that a child has taken a poison of some sort, it may be known what has been taken, or it may not be known. We will consider first

Unknown Poisons.—If the child should vomit, this should be encouraged; if not, it must be provoked. The simplest way to do this is to give large draughts of lukewarm water, and to titillate the fauces. If there is time, and it is at hand, a teaspoonful or two of ground mustard may be stirred up in the water, or a teaspoonful of powdered ipecac, or a tablespoonful of the syrup of ipecac. There is no occasion for fastidiousness. Any water will do. Water in which hands—or dishes, for that matter—

have been washed, may by its very repulsiveness act more quickly than anything else; and if soap has been used, it will be all the better for that, as soap is an antidote for acid poisons. The quantity used must be large; the sufferer must be urged to drink and drink, a large quantity at a time, until he can contain no more, and has been made to vomit over and over again.

After copious vomiting, soothing liquids should be given,—oil, milk, beaten-up raw eggs,—all in moderately large quantities. These are especially valuable when the poison has been of an irritating character.

If the sufferer be much depressed, some stimulant may be administered. Strong, hot tea, without milk, is the best, because it is a chemical antidote to many poisons. Strong coffee is next in value. To either of these can be added brandy, whiskey, wine, or alcohol, in half-teaspoonful doses, mixed with a little hot water. Warm coverings are not to be forgotten; and if the depression be great, hot-water cans or hot bricks, wrapped in one or two thicknesses of blanket, should be laid by the side of the chest, or a large poultice placed round the body, or a blanket wrung out of hot water and covered with a dry one.

Mineral Acids.—For these the proper treatment is to give an alkali. A tablespoonful of hartshorn may be mixed with two teacupfuls of water, and given; or almost unlimited quantities of soda, magnesia, potash, whitewash, chalk, tooth-powder, whiting, plaster, soap, or even wood-ashes, stirred up in water. After this should come the provoking of vomiting; then the bland fluids mentioned above should be administered, rest secured, and stimulation employed if necessary.

Oxalic Acid.—For this the best antidote is lime in some form. If lime-water is at hand, it may be given freely, or whitewash, tooth-powder, chalk, whiting, or plaster from a wall. The latter may be crushed and stirred up in water, without regard to the grittiness, which will not do any harm.

Carbolic Acid is a very dangerous poison, because it acts rapidly and benumbs the stomach, so that it is hard to provoke vomiting. This must be attempted, however, and large draughts of oil, white of egg, magnesia and water, or milk must be given. Rest, warmth of the body, and stimulation must also be secured.

Alkaline Poisons.—Strong alkalies must be combated with an acid. Vinegar can always be had, and there is nothing better. It should be given undiluted and in large quantities. Lemon-juice may be used, or even orange-juice, though the latter is too mild an acid to be of much service, unless the oranges are very sour. Vomiting should then be provoked, and followed by bland drinks, rest, and stimulation if necessary.

Arsenic usually excites vomiting and violent pain in the stomach. At once large quantities of milk, white of egg, flour-and-water, or oil and lime-water must be given. The vomiting must be encouraged or provoked, and dialyzed iron should be given freely, in tablespoonful doses, each dose being followed at once by a teaspoonful of common salt in a teacupful of water; or, if this is not at hand, equal parts of sulphate of iron and of carbonate of sodium may be dissolved in separate cups of hot water and then mixed and drunk. Afterwards vomiting should be again provoked, and followed by a dose of castor oil.

Acetate of lead calls for vomiting, Epsom salt, milk, eggs, and castor oil.

Corrosive Sublimate.—When this is taken, vomiting must be provoked, and some form of tannic acid given. Strong tea is the handiest thing containing this, and its administration should be followed up with eggs and milk.

Tartar emetic is best treated in the same way.

Phosphorus is sometimes chewed off matches by children. It is a poison which acts slowly. Five-grain doses of sulphate of copper dissolved in water may be given, at intervals of ten minutes, until vomiting comes on. Then a dose of magnesia should be administered, but *no oil.*

Nitrate of Silver.—The antidote for lunar caustic is a very strong brine of salt-and-water, given again and again; and vomiting should be provoked until the vomited matters cease to have a look like thin milk.

Iodine, in the form of a tincture, is also sometimes swallowed by mistake. The antidote for this is starch-and-water.

Opium preparations, such as opium, morphine, laudanum, paregoric, black drop, must be combated with emetics, used promptly. Strong coffee must be freely given as a stimulant. So long as the breathing does not fall below ten to the minute, there is no *immediate* danger of death; but the important matter is to keep up the breathing. The custom of walking a patient up and down and slapping him with wet towels is to be deprecated, because it adds exhaustion to stupor. If an electrical battery can be obtained, the faradic current should be used, and applied so as to stimulate the sensory nerves in the skin, so that they shall excite reflex acts of deep breathing. The next best thing is to lay the patient upon a lounge and slap his skin with the back of a broad brush or with a slipper. This is all the rousing that is necessary, so long as the breathing keeps above ten to the minute. Should it fall below this, or if the breathing should cease, artificial respiration should be employed.

Chloral.—The treatment for chloral poisoning is the same as for poisoning by opium.

Strychnine poisoning should be treated by provoking vomiting, giving a purge, and doses of fifteen grains of bromide of potassium or ten grains of chloral, or both. The greatest quiet must be secured. The poisoned person should be put to bed in a darkened room, with doors, windows, and shutters arranged in a way that shall exclude all sights, sounds, and draughts, though permitting good ventilation.

Aconite.—In case of aconite poisoning vomiting must be brought on, and followed by the administration of stimulants. Strong coffee may be used, hartshorn (a teaspoonful in a teacupful of water), wine, whiskey, or brandy. If there is depression, warmth should be used, as described when speaking of unknown poisons.

Veratrum viride poisoning is to be treated like aconite poisoning.

Hemlock, deadly nightshade, the Jamestown (or jimson) weed, monkshood, and toadstools are sometimes eaten, without knowledge of their poisonous character. **Tobacco**, too, sometimes causes poisonous effects. All produce deep depression, and must be treated by the induction of vomiting, if it has not already occurred, followed by stimulation and warmth, very much as in the case of aconite poisoning.

Alcoholic liquors are sometimes taken in such large quantities as to be poisonous. When this is the case the course to be pursued is to cause vomiting, give hartshorn-and-water (a teaspoonful in a teacupful), and keep the body warm.

Decayed meats or vegetables usually excite vomiting, which should be encouraged till the stomach is empty, and followed by a dose of castor oil and some powdered charcoal.

In conclusion, let it be remembered that when there is an alarm of poisoning it is important to *keep cool.* In many cases of poisoning there is much more alarm than danger. Death from accidental poisoning is very rare. To save time in an emergency, the following table may be consulted, which gives the name of each of the poisons we have already studied, and the proper treatment for it.

Poison.	Treatment.	
Unknown	Provoke repeated vomiting; Give bland liquids; Stimulate, if necessary.	
Acids: Sulphuric, Nitric, Muriatic, Oxalic, Carbolic,	Give an alkali; Provoke vomiting; Give bland liquids; Secure rest; Stimulate, if necessary.	
Alkalies: Hartshorn, Soda, Potash, Lye,	Give an acid (vinegar); Provoke vomiting; Give bland liquids; Secure rest; Stimulate, if necessary.	
Arsenic: Paris green, Scheele's green,	Provoke vomiting; Give dialyzed iron and salt;	repeat several times;
	Give dose of castor oil; Secure rest; Stimulate, if necessary.	
Acetate of Lead: Sugar of Lead,	Give Epsom salt; Provoke vomiting;	repeat several times;
	Give bland liquids; Give dose of castor oil.	
Corrosive Sublimate, *Tartar Emetic,*	Provoke vomiting; Give strong tea, without milk;	repeat several times;
	Give raw eggs and milk; Give dose of castor oil; Stimulate, if necessary.	

POISON.	TREATMENT.
Phosphorus	Provoke vomiting; Give five-grain doses of sulphate of copper, or teaspoonful doses of turpentine. Give dose of magnesia, but *no* oil.
Nitrate of Silver	Give strong salt-and-water; Provoke vomiting; repeat many times.
Iodine	Provoke vomiting; Give starch-and-water; Give bland fluids.
Opium: Morphine, Laudanum, Paregoric, etc., *Chloral,*	Provoke vomiting repeatedly; Give strong coffee, without milk; Keep up the breathing.
Strychnine	Provoke vomiting once or twice; Give a purgative; Secure absolute quiet.
Aconite, *Veratrum Viride,*	Provoke vomiting; Stimulate well; Keep head low.
Jamestown Weed, *Hemlock,* *Nightshade (belladonna),* *Toadstools,* *Tobacco,*	Provoke vomiting; Stimulate well.
Alcohol	Provoke vomiting; Give hartshorn-and-water.
Decayed Meat or Vegetables	Provoke vomiting; Give a purgative; Give powdered charcoal.

To provoke vomiting, warm water may be used, with or without ground mustard (a teaspoonful to half a pint of water), or ipecacuanha (a teaspoonful of the powder or a tablespoonful or so of the syrup), and titillating the fauces. It is best to give large quantities (half a pint at a time) of warm water whenever vomiting is to be excited.

Bland liquids are milk, raw eggs, some sort of oil, gruel, etc.

Stimulants are tea, coffee, whiskey, wine, etc., or hartshorn-and-water. A teaspoonful of hartshorn in a teacupful of water will be enough for a dose. In making tea or coffee one must not wait to do it as if for the table, but mix hot water and the leaves or grounds, squeeze them well, stir together, and give the whole,—leaves, grounds, everything. At the same time, some may be made regularly, if there are conveniences for it.

Alkaline antidotes are hartshorn-and-water (a tablespoonful in two teacupfuls of water), soap-and-water, lime, whiting, soda, chalk, tooth-powder, plaster, magnesia, whitewash, and even wood-ashes.

Acid antidotes are vinegar and lemon-juice.

In giving an antidote, never wait for it to dissolve. Just stir it up in any fluid at hand, except oil, and have it swallowed immediately.

PLASTIC SURGERY.

BY THOMAS G. MORTON, M.D.

THE term "plastics" or "plastic surgery" has been made to cover a wide range of procedures which are in the main reparative, formative, or reconstructive; in other words, such as have for their primary or principal object the remedying of natural physical defects, or the restoration of lost tissues or organs or parts of organs, including operations extending from skin-grafting to transfusion of blood.

Although such operations are occasionally referred to in the writings of the ancients, and have been practised by the Hindoos and Egyptians from time immemorial,[1] it has been only during the last half-century that general surgery has advanced to a position that would permit the development of plastic surgery into a distinct department of medical science. Stimulated by the subcutaneous division of tendons by Stromeyer, about 1831, and by the discovery of skin-grafting by Reverdin, in 1869, plastic surgery may be said to have entered upon a new era with the advent of anæsthetics and antiseptic methods into surgery. By the former, absolute control of the patient is afforded; by the latter, the successful result (or at least the prevention of suppuration) can generally, if not invariably, be assured. At the same time, the proportion of cases requiring plastic operations is very much smaller than formerly, because the methods pursued in the modern treatment of wounds prevent suppuration and loss of tissue after operation; and, since mercury is now given with less freedom, instances of ulcerative stomatitis with sloughing of the lips or cheek rarely, if ever, occur. Plastic operations are infrequent in children, and most of them will be found described elsewhere in this work under appropriate headings,—"Congenital Defects and Deformities of the Face, Lips, Mouth, Tongue, and Jaws," "Hare-Lip and Cleft Palate," "Congenital Affections of the Bladder and Penis," "Club-Foot and Torticollis," "Deformities of Bone," etc.,—and need not be further referred to in this paper.

The principles involved in plastic surgery of childhood in no way differ from those governing similar operations at any other period of life.

The preparatory treatment is all-important: indeed, we may lay down the rule that a condition of the tissues favorable to repair is absolutely necessary for a successful result. A plastic operation should not be considered, nor undertaken, unless the disease necessitating it is practically eradicated.

---

[1] Ashhurst's Encyclopædia of Surgery, vol. i.

The conditions of the operation and surroundings and the after-treatment likewise should be such as will most readily conduce to success. Sufficient care must be exercised to secure rest for the part operated upon and proper nourishment to the transplanted tissue; there must also be no strain upon the flap, which should be of ample proportions; and, moreover, thorough antiseptic precautions should always be carried out.

Congenital defects do not generally yield as good results as acquired ones; but it is to be observed that where the skin has been destroyed by burns or scalds, the new tissue never exhibits the same anatomical characters as the old, and usually does not possess the vitality of the surrounding skin. Operations requiring transplantation of flaps of skin are rarely performed at the present day. On account of the miserable results obtained by the rhinoplastic and other methods of restoring lost noses, such operations are held in rather low estimation, and the opinion gains among operators of most experience that the very admirable artificial noses which are now made are in every way superior, and, when compared with the results of rhinoplasty, far less objectionable.

In performing plastic operations the operator should avail himself of true skin in order to have a successful result. Skin-grafting, by using small pieces of epidermis or scrapings of the skin, in the treatment of ulcers, is a well-established procedure in surgery, and need not be described, as it is performed in the child in precisely the same manner as in the adult. The same may be said of transplantation of bone-fragments in cases of ununited fracture, to replace osseous tissue and stimulate union where the ends of the divided bone are even widely separated. An extemporaneous plastic operation is occasionally required when the edges of a wound will not approximate unless with an extreme amount of tension, which may be sufficient to threaten the vitality of the flaps. In such a case part of the wound may be left to granulate and gradually cicatrize, or the operator may at once transplant a portion of skin to fill up the cleft and thus avoid the production of a large or a contracted cicatrix. Where this is not done at the time of operation it may be resorted to later, as by Reverdin's method of transplanting skin upon the surface of open wounds. The same procedure may be called for after there has been absorption of the flap or loss of part of it from gangrene.

Recently efforts have been made to improve vision by transplanting the healthy cornea of the rabbit upon the human eye, but thus far the operations which on several occasions have been performed have not been attended with any success. When the graft has become vitalized it has become opaque; it is not only useless, but is also a blemish, even worse than the condition it was designed to remedy.

There are some precautions to be observed in operations requiring transplantation of flaps of skin, such as those performed to save an eyeball from destructive inflammation, those to remedy various deformities of the eyelids by scars, those to afford relief in cases of exstrophy of the bladder, etc. The flaps should in all cases contain a fair supply of blood-vessels and cellular tissue, they should be large enough to allow for shrinkage, and scar-tissue should be avoided. When it becomes necessary to twist the flap, great care should be taken that it be placed so as to avoid all tension, or, if that is impossible, so as to exert the least possible strain, in order that there shall be little or no interference with the circulation; all tension is injurious. Large blood-clots should be removed, so that there shall be fairly close approximation of the raw surfaces; and strict antiseptic precautions should prevail.

In performing the open incision for club-foot, often a wide gap is left when the deformity is corrected, and incident to the healing of this considerable contraction occurs: to avoid this and a recurrence of the varus, I have suggested and performed transplantation of a flap of skin from the dorsum of the foot.

Dressing.—Unusual care should be observed by the surgeon and his assistant as to personal cleanliness and the preparation of the necessary instruments and dressings. The mercuric-chloride solutions afford the greatest protection, and should be freely used before, during, and after the operation. While the operation is in progress a douche of distilled or recently-boiled water can be substituted for the mercuric solution.

All the instruments should be boiled before being used, and all ligatures, carefully selected and prepared for the operation, should be kept in a weak carbolic solution. The line of sutures after the wound is closed, as well as the drain, should be covered by a narrow strip of protective; the gauze dressing, wrung out of a weak mercuric solution, is next applied; the gauze bandages should be of a light, fine, soft material, and also kept in a weak mercuric solution. Where there is a probability of considerable oozing, the dressing should then be covered with bichloride absorbent cotton, and this retained in position by dry, gauze, bichloride bandages. Very free or troublesome oozing of blood from the raw wound-surfaces may be readily controlled by the use of hot water or of a solution of the peroxide of hydrogen. It is always better to avoid ligatures if possible; if necessary, fine gut should be used. Occasionally a drain of gut, or in certain cases one of rubber, may be required. Owing to the irritability of the skin in children, only very weak solutions of bichloride of mercury (one in three thousand or one in four thousand, or even of less strength) should be employed. The field of operation should be surrounded by towels wrung out of warm mercuric solution. Before the operation the wound and the skin to be transplanted should always be carefully cleansed with soap and water, the surface shaved, then washed with turpentine and ether, and lastly well douched with the mercuric solution; in other words, the strict antiseptic precautions which are demanded in all surgical operations should be adopted.

By this means immediate union of the transplanted tissues is generally secured, which is particularly important in all plastic work.

In this place it will not be necessary to describe in detail the manner of executing the various formative or plastic operations, or to discuss further the technique of the dressing of the wound. It is proper to state, however, that if the operation be of any gravity an anæsthetic will be required, in order to prevent the surgeon from being disturbed by the cries and struggles of the little patient. Nitrous oxide does well for short operations; in more protracted ones chloroform or ether may be used,—preferably the latter. Chloroform, however, is far less dangerous in infancy than in later years, but under any circumstances it should be given with great care and a very free admixture of air allowed, so that the vapor of chloroform shall not be present in the inspired air in larger proportion than from three to five per cent. For tedious operations the best washed ether should alone be used. In such as promise to be unusually protracted, mixed anæsthesia may be resorted to, either by the preliminary administration of alcohol (whiskey, brandy, or wine) or by the method of Nussbaum,—the hypodermic injection of morphine. In the latter case, on account of the well-known want of tolerance of children to morphine, the dose should be very small, and might properly be accompanied by atropine; or in very young children atropine alone, or belladonna, should be administered in place of morphine. However, in the use of such agents in children for this purpose the writer has no personal experience to speak from.

Plastic operations are called for in children for two classes of cases,—(1) to correct congenital malformations or deformities, and (2) to remedy lesions resulting from disease or traumatism.

Of the former class the following may be cited: 1, webbed fingers and toes, and the like; 2, hare-lip and cleft palate; 3, imperforate anus, nares, or auditory canal; 4, exstrophy of the bladder; 5, congenital hernia; 6, spina bifida; 7, sinuses, branchial and others; 8, various malformations of the genital organs; 9, abnormalities of the eye and its coverings; 10, some conditions of club-foot, etc.

Among the lesions produced by disease or traumatism requiring plastic operations in childhood the most frequent are—1, contracting cicatrices (from burns, caustics, ulcers, etc.); 2, loss of portions of the body by sloughing (as of the lips, cheeks, or vulva) from the abuse of remedial agents (mercury), or following acute eruptive fevers (measles, small-pox, etc.); 3, mutilation or loss of parts of organs by traumatism (ears, nose, lips, etc.), or the development of fistulous tracts after various forms of disease or injury (urethral, perineal, etc.).

WOUNDS.

BY JAMES McCANN, M.D.

THE injuries to which children are liable do not differ in any important feature from those which are sustained by grown persons. In their immediate effects, however, as well as in their remote consequences, there are many points of divergence.

Shock—"that depression of all the vital functions which follows a severe injury," at all periods of life—is peculiarly intense in early childhood, especially when associated with terror, long-continued and severe pain, exposure to cold, or loss of blood. Reaction, however, is usually prompt, and when once fairly established is not followed by the fatal secondary depression so often encountered in the injuries of adults.

In its mildest form it appears as a mere temporary disturbance of the functions of the nervous system, manifested by dizziness, faintness, and trembling. This mild form disappears spontaneously. In its severer form it causes symptoms of the most alarming character, indicating the peril in which the child is placed. These symptoms are usually very characteristic. "All the nervous and circulatory functions are in a state of collapse." The child lies in a state of semi-stupor, or tosses from side to side in extreme restlessness. The face is usually pale and death-like, the lips livid, the eyes glassy, the body cold and damp with perspiration, the pulse small, very frequent, feeble, or imperceptible, and the respiration shallow, sighing, or moaning; convulsions are not uncommon in very young children. Thirst is generally a distressing symptom (when the stupor is not too profound), and the efforts to relieve it are frequently rendered ineffectual by persistent vomiting. Death may occur from shock alone, independent of hemorrhage, extent of injury, or lesion of important viscera. Fortunately, this perilous condition is usually of short duration; reaction soon appears, the pulse becomes fuller and stronger, warmth returns to the body, and the face regains its normal color and expression.

When shock is severe, reaction should be hastened by placing the child in a perfectly horizontal position, with the head low, and by the application of dry warmth to the extremities and the administration of diffusible stimulants. Brandy or whiskey in half-teaspoonful doses may be given every half-hour or hour to a child of two years, with hot milk or broth, and, if the depression be extreme, large enemata of water at a temperature of 106–110° F. should be used. All bleeding must be checked, for continued hemorrhage, even if moderate, will greatly delay reaction.

Acute pain, which is so distressing a symptom of many injuries at all ages, is especially depressing in its effect in childhood, and tends to prolong and intensify shock. Hence anodynes and anæsthetics are often required to lull the pain following an accident, as well as the inevitable suffering caused in the dressing of severe injuries.

Primary hemorrhage is at times very disastrous in its immediate effects in early childhood: all the tissues are exceedingly vascular, and every severed vessel bleeds furiously. The flow of blood, however, is nearly always easily controlled, and, once arrested, shows little tendency to recur.

Secondary hemorrhage is very rare except when there is extensive and rapidly-destructive ulceration or suppuration. The hemorrhagic diathesis is not peculiar to early life.

Although rather high febrile excitement follows all severe injuries and operations in childhood, its duration is brief, and gangrene, ulceration, and profuse suppuration, as immediate results of injuries, are very rare except when the main vessels and nerves of the limb are destroyed, the tissues reduced to a pulp, or a joint penetrated. Children are, indeed, remarkably free from those profound traumatic constitutional disturbances so commonly met with in the adult; and hence sapræmia, septicæmia, and pyæmia are less frequent and less formidable complications of injuries, while the severe forms of erysipelas and phagedæna are almost unknown. Mild or cutaneous erysipelas, however, is not very uncommon.

While there is marked freedom from all the lethal complications which so commonly follow severe injuries in the adult, the remote effects manifest themselves by various structural changes. Chronic indurations and low sluggish forms of inflammation, ending in caseous degeneration or in tedious and exhausting suppuration, are common sequels of wounds in children. Not infrequently the damaged part becomes the focus of malignant degeneration, especially sarcoma.

Owing to the perfection of the nutritive processes and the almost universal absence of the visceral and vascular degenerations common in adult life, repair goes on in childhood with surprising rapidity and perfection; the most extensive wounds heal quickly and uninterruptedly, even in very unfavorable cases; badly bruised and torn structures retain their vitality, or regain it when apparently devitalized, and are often unexpectedly reunited. So intense is the physiological activity of the tissues of the child that repair after injury, except in very extreme cases, can be confidently looked for, and no tissue should ever be hastily sacrificed, no matter how badly it appears to be damaged. When an entire limb is so badly mangled that it is doubtful whether it is wiser to try to save it or proceed at once to amputation, the advice of Mr. Holmes should be followed: "In compound fracture, amputation should never be practised except when the limb is hopelessly crushed and disorganized. In all doubtful cases the limb ought to be preserved until the onset of gangrene renders the effort to save it no longer justifiable."[1]

The bad sanitary conditions which surround the children of the poor exert no markedly injurious influence upon the healing of their wounds. The so-called "strumous" or scrofulous diathesis cannot be regarded as militating against necessary operations, nor as retarding recovery after accident. The success which follows removal by operation of the profusely-discharging surfaces of chronic suppurative synovitis or ulcerating glands affords striking evidence of the power which children possess not only to repair injuries and to recover from formidable operations, but also to regain health as soon as the source of irritation and exhaustion is removed.

REPAIR OF WOUNDS.

The healing process in all varieties of wounds is accomplished by changes in the nutrition of the parts, which result in the development of new tissues from material supplied by the old. "A wound is a solution of continuity of the external soft parts." The newly-formed tissue is the bond that unites the divided parts which retain or regain their vitality, and makes good the loss of tissues disorganized beyond recovery by the original violence or subsequent suppuration. The quantity of new tissue, obviously, varies greatly in different wounds. The healing process, though essentially the same, varies considerably with the quantity of tissue lost, the treatment employed, and the special circumstances of the case. The new tissue is at first embryonic, and then passes rapidly through the intermediate stages of development to the mature tissues of the cicatrix. The original structures surrounding the wound also return more or less to the embryonic condition and become continuous with the new tissues uniting them. The whole complex process may be regarded as "growth followed by organization."

Whatever determines the variations of the healing process, clinically it follows one or other of five methods,—viz., first, by immediate union; second, by primary adhesion, or union by first intention; third, by granulation, or union by second intention, accompanied often by suppuration; fourth, by union of granulations; and, fifth, by union under a scab. This is the classification of Macartney, and is adopted by Paget.

1. **Immediate union** is extremely rare, though occasionally secured in clean incised wounds which are promptly and accurately coaptated and kept absolutely at rest: The divided ends of the various structures in the opposite walls of the wound unite again immediately, without appreciable inflammation or febrile excitement. They become continuous without the development of a bond of new tissue between them, and the process is, of course, free from the symptoms arising from its development and the acci-

---

[1] Surgical Diseases of Children, p. 242.

dents which befall it. The time required is much shorter; union is complete in from twenty-four to forty-eight hours, and there is no visible scar. This method of union requires an almost unattainable accuracy in the adjustment of each severed tissue, the wound itself must be absolutely free from all foreign bodies, blood, or clots, and there must be perfect asepsis. It is the ideal mode of repair, and should always be sought, but can very rarely be attained.

2. **Union by primary adhesion,** "adhesive union," or "healing by first intention," is the most frequent as well as the best attainable method of repair of incised wounds. It is less frequent in other forms. Following every wound in which the conditions requisite for immediate union do not exist, there is a brief period of calm, during which all the hemorrhage ceases and the reparative processes have not begun. This stage of quiescence is quickly succeeded by an active dilatation of the vessels in the vicinity, and by a copious migration of leucocytes, red blood-corpuscles, and hæmatoblasts from the gorged capillaries, which together with the exuded liquor sanguinis infiltrate the tissues immediately surrounding the wound and appear as a glossy film, "glazing" its surfaces. In a few hours this glazed appearance changes first to a grayish and then to a pinkish white, and a covering of soft adhesive material is visible on the surface. Organization has now begun in the exudate. This covering is embryonic granulation-tissue, which the microscope shows to be rich in lymph-corpuscles and other cells in various stages of development into the types found in mature granulation-tissue. The borders of the wound now become swollen, soft, and juicy, its lips pout, and a serous or sero-sanguinolent fluid escapes from it. If it is aseptic, and at this stage its edges be accurately approximated, they will unite by a process not very different from immediate union. Ordinarily this is prevented by a film or clot of blood, which, although affording some protection against putrefaction and serving to hold the wound together, prevents close contact of its walls, and consequently repair cannot be perfect until it disappears or is removed. Its removal is effected very soon by natural processes. The clot is rapidly infiltrated by leucocytes, the red corpuscles disappear, the fibrinous net-work which formed its basis softens and is in part changed into a homogeneous mass which blends with the lymph covering the wound-surfaces. The round cells of the exudate very early become club-shaped, fusiform, or branched, with attenuated extremities which arrange themselves in interlacing bundles. In this way the opposite surfaces of the wound are brought together by new fibro-connective tissue.

Vascularization occurs by the development of new capillaries in the organizing exudate from the dilated and tortuous vessels of the walls of the wound. Starting probably from their endothelial cells, bud-like offshoots are seen very early in the evolution of the new tissue; a little later, thread-like processes push their way through the soft embryonic granulation-tissue uniting the wound until they meet other processes like themselves or the original capillaries. They join at the point of contact; the central portion liquefies, forming a tube continuous with the lumen of the capillaries on each side. The new channels at first transmit only plasma, but soon dilate enough to permit the corpuscles to pass. The walls of these rudimentary capillaries acquire strength through the adhesion of new particles of protoplasm and the rapid development of fibroblasts upon their free surface. Endothelial plates are developed from the leucocytes which adhere to the inner surface of the new-formed vessel. A new vascular bond is thus formed, rudimentary at first, but in a few days presenting all the histological peculiarities of the normal capillaries.

As the new bond of union organizes and becomes vascular, the cells of the skin at the margins of the wound proliferate rapidly. Owing to the constant tendency of all impaired tissues to reproduce structures similar to the part lost, young epidermic cells are formed. Their presence is indicated by a bluish-pink line bordering the edges of the wound and advancing towards the central line, where union of the opposite borders occurs, which completes the scar superficially. Organization in the deeper parts is slower, and is followed by contraction of the new fibro-connective tissue. The general obliteration of the new capillaries by this contraction restores the part to its normal color.

3. **Healing by granulation**, or by second intention, occurs when, as a result of improper closure of the wound, of too long exposure of its surface to the air, of loss of substance, or of extent of injury, repair by the methods just described fails. Hemorrhage is arrested by coagulation of the blood in the injured capillaries, extending as far as their first branches. A temporary local stagnation comes first, which effectually stops all bleeding. An exudate from the vessels poured out into the perivascular and interstitial spaces bathes the surfaces of the cavity of the wound and saturates the dressing with a thin, reddish-yellow, serous or sanious fluid.

If this fluid is allowed to become infected, it decomposes, and irritates the wound, and may give rise to constitutional septic infection. The discharge in this case is converted into pus, and the unfortunate change is betrayed by the offensive odor coming from the dressings. When it escapes infection, the exudate coagulates, and covers the surface with a grayish-white or ashy gray, viscid, albuminous film of plastic lymph. The connective-tissue corpuscles and muscle-cells proliferate with great rapidity. The surrounding tissues become gelatinous, and the edges are hot, swollen, and juicy. New capillaries are formed from the old; those nearest the surface travel in the direction of least resistance, push their way in vascular loops into the soft adhesive glaze which covers the wound, and appear as minute red points dotting its surface. These new capillary loops return the blood to the parent vessels.[1]

---

[1] Hamilton, of Aberdeen, in his recent work, "Text-Book of Pathology," declares that these vascular loops are merely the original capillaries elongated by the blood-pressure no longer counteracted by the tension of the skin.

This process continues until the entire wound-surface is transformed into a soft, ruddy, highly vascular mass of embryonic granulation-tissue, which blends intimately with the underlying structures. An active outgrowth of epithelioid cells or fibroblasts, derived undoubtedly from the proliferating connective-tissue corpuscles, together with a part of the migrated leucocytes, develops into bundles of interlacing fibrils and forms a framework of young fibro-connective tissue throughout the granulating surface.

Thus far the process is perfectly physiological: the thin film which covers the granulations, though it may be rich in dead leucocytes, is bland and unirritating, and free from micro-organisms. It is strictly a dead inflammatory exudation, but not suppuration. Suppuration forms no necessary part of the healing process; its occurrence indicates that pathological changes have supplanted physiological repair, and that the wound is no longer aseptic.

It is inevitable that a part of the superficial formative elements should lose their vitality, because of their remoteness from the channels of nutritive supply, the mechanical irritation of the dressings, or the corrosive effects of the antiseptics with which they are charged. This débris, mingling with the sanguinolent serous fluid which moistens the surface of the granulations, appears as a discharge, seldom abundant in purely aseptic wounds. When present it is a pinkish-yellow, watery fluid, which under the microscope shows the presence of dead leucocytes, in this respect resembling pus; but the fluid differs from that of suppuration, in the absence of specific micrococci, which are an essential etiological factor of the latter process.

If contact with unsterilized instruments or other objects or with the atmosphere—which usually contains the staphylococcus pyogenes aureus, albus, and citreus, or the streptococcus pyogenes—is not avoided, these micro-organisms, finding a suitable habitat, increase rapidly in numbers, and, irritating the surface of the granulations, cause increased vascularity and an abnormal outflow of plasma, leucocytes, and the like. Under their influence the leucocytes die and become pus-corpuscles, and the exuded elements are rendered incapable of coagulation; the granulations are covered with a film of so-called laudable pus, which greatly retards the healing process, though it seldom prevents it.

Cicatrization commences by the generation of young epidermic cells from the old ones at the margins of the wound. The young cells are more or less rounded in form, and resemble those of the rete Malpighi. "They do not really adhere to the underlying surface, but throw down long processes, which pierce the tissue underneath, and thus adhere to it."[1] They give rise to a bluish-pink film or pellicle, which gradually spreads from the margins over the granulations until the whole surface of the wound is covered by a rudimentary epithelium. The process is hastened by the contraction of the new connective-tissue in the deeper parts of the wound, which draws its edges together. This process of deep cicatrization continues until repair is complete in the entire wound. The scar is larger and more distinct than that which follows in healing by primary adhesion, but without other difference. The color is restored in the same way, by obliteration of the capillaries, which is often so complete that the scar is white and appears bloodless. It becomes pliable and elastic, but remains during life.

---

[1] Hamilton, op. cit.

When devitalized tissues or foreign bodies are retained in the wound, the healing process is retarded. If the wound can be kept in a perfectly aseptic condition, and is properly drained, the growth of new granulation-tissue goes on uninterruptedly; the devitalized tissue is separated from the living structures by the formation of a border of young granulations,—"a zone of demarcation,"—and the dead portion occupies a position on the surface somewhat similar to that of a scab, and a species of "desiccation" goes on underneath. When an insoluble foreign body remains in the wound, it is first surrounded by a zone of inflammatory infiltration: this undergoes organization into granulation-tissue and then into a fibrous capsule, and the foreign body becomes encapsulated or encysted.

If, however, the wound is not properly drained, and if through imperfect antisepsis the retained discharges become infected by any of the germs of suppuration or putrefaction, inflammation is at once intensified, and increased exudation of leucocytes and plasma bathes the surface of the wound with pus. The dead tissues separate by an ulcerative process, purulent infiltration invades the surrounding structures, and the dangers of septic absorption and general blood-pollution are immeasurably increased.

4. **Repair by union of granulations**, or by "secondary adhesion," occurs when two granulating surfaces are held in contact either by surgical appliances or by the growth of the granulations themselves. New connective tissue is formed and unites apposed granulations; and capillaries are formed by union of vascular processes derived from those of each surface. Cicatrization completes the process of repair by union of granulations.

5. **Healing under a scab**, or "subcutaneous cicatrization," resembles union by primary adhesion, and, next to that, is the most favorable mode of repair. A perfectly aseptic wound is hermetically sealed by its own exudation. Blood and serum collect and dry upon the surface in such a manner as to form an impervious covering for the wound; air and septic materials are excluded, and the severed structures unite with an almost imperceptible degree of inflammation, and with the formation of a delicate and unindurated scar. The wounds of animals heal in this way. It is a very desirable mode of repair. The crusts which form on a wound, especially of the face, should not be disturbed until they become so loose as to be ready to drop off. If the scab be removed too soon, a second scab does not form, and the wound heals by granulation.

DEFINITION AND CLASSIFICATION.

"A wound is a solution of continuity of the external soft parts, recent, and the result of violence." For convenience, the wounds of children, like those of adults, are primarily divided into open and subcutaneous, and are further classified as incised, contused, punctured, and poisoned wounds.

INCISED WOUNDS.

The incised wound is the form most frequently encountered. It is an injury inflicted accidentally or intentionally by any sharp-edged instrument or weapon, as a knife, razor, chisel, axe, sharp fragment of glass or bone, etc. The tissues are all smoothly severed, without appreciable injury to those in the immediate vicinity. The symptoms which distinguish incised wounds are pain, hemorrhage, and gaping or separation of the divided structures. The pain is usually sharp, cutting, and very severe at first, then burning or smarting, and finally subsides into a dull aching sensation, with more or less stiffness of the affected part. It varies in intensity in different portions of the body. Most painful are wounds of the face and lips, of the palms of the hands and soles of the feet, and of the arms and genitals. When severe and long continued, pain becomes extremely depressing and adds to the intensity of the shock.

Hemorrhage is always profuse at first, on account of the clean division of the blood-vessels; the blood pours from the whole surface of the wound; when an artery is divided, it spins or spurts furiously at single points in a bright red stream, *per saltum*, as if thrown from the nozzle of a syringe. Such a hemorrhage may soon destroy the life of a child. The blood from an incised or a divided vein wells up from the wound in a sluggish stream, dark purple in color, and accelerated during expiration if one of the large venous trunks in the neck is wounded, and death from hemorrhage or from entrance of air into the vein may occur before assistance can be obtained.

Gaping or separation of the edges depends upon the elasticity of the skin, the situation of the wound, and its relation to the fibres of the underlying muscles. Wounds which are transverse to the long axis of a limb gape more widely than those parallel to it, while if the underlying muscles be involved the retraction of the severed fibres will be greater than that of the skin, causing a deep cavity wider at the bottom than at the surface. Great care is required in closing such a wound, lest a pocket be left in which blood and discharges will collect, which not only prevent the healing process, but also, by decomposing, expose the patient to danger from septic absorption. Wounds of the face, when deep, display a great tendency to gape widely, because of the elasticity of the skin and its firm attachment to the subjacent muscles; and this tendency is aggravated by the violent contraction of the facial muscles when the child cries. Much patience and skill are required in closing these wounds, to prevent disfiguring scars; and sutures when used should be closely inserted, and reinforced by strips of aseptic adhesive plaster and carefully-adjusted compresses and bandages.

The shock which follows all forms of incised wounds depends for its intensity and duration upon the depth and location of the wound, the nature of the divided structures, and the presence or absence of hemorrhage. Reaction should be hastened by the measures set forth in the beginning of this article.

TREATMENT OF INCISED WOUNDS.

The primary object in the treatment of all wounds is to secure rapid, painless, and complete repair of the damaged parts. To accomplish this, an effort should be made to secure union by primary adhesion wherever possible. "*Union occurs in every aseptic wound the surfaces of which are brought into exact apposition.*" (Trélat.)

It is assumed at the very beginning that every detail of the treatment of all forms of wounds, from the moment of infliction until the end of the healing process, shall be carried out with the strictest regard to the conditions of asepsis. For this purpose it is absolutely necessary not only that the wound shall be clean, but also that the skin contiguous to it shall be thoroughly scrubbed with soap-and-water and afterwards bathed and irrigated with some antiseptic solution. The hands of the surgeon and his assistants must be rendered absolutely free from every possible source of contamination, all instruments, sutures, and the like, liable to come in contact with the wounded tissues, must be taken directly from a germicide solution, and the external dressings must be so charged with one or other of the many antiseptics now in use that they will protect the surface of the wound from contact with the air and prevent the occurrence of putrefaction in the discharges. Attention to details is of the utmost importance, and strict cleanliness is of far greater value than a cumbrous paraphernalia of instruments and dressings.

The indications of treatment are to arrest hemorrhage, to cleanse the wound, to provide for its drainage, to secure apposition of its surfaces, to protect it from the entrance of septic or putrefactive germs, and to secure absolute rest for the damaged part.

Arrest of Hemorrhage.—Although the blood pours out freely at first from the whole surface of an incised wound, its force soon abates, unless a large artery is divided. The ends of the smaller vessels contract spontaneously upon exposure to the air or to a stream of cold water, and cease to bleed. Elevation of the part and moderate pressure upon the surface of the wound hasten this result. Hot water—115° to 120° F.—produces a similar effect, by stimulating the divided vessels to contract, and possibly also by coagulating the albumen of the blood. Bleeding from larger arterial branches will usually require special measures,—the ligature, torsion, pressure, etc.

Torsion is certainly the most rapid, efficient, and safe method of permanently controlling hemorrhage at all periods of life, but especially in childhood, which the surgeon has at his command. An extensive experience with this measure in the surgical wards of the Western Pennsylvania Hospital has demonstrated its superiority over other methods of controlling hemorrhage, and fully confirmed Mr. Bryant's opinion of its value. During the past sixteen years it has been relied upon almost exclusively in that institution, and it has frequently been applied to the brachial, axillary, popliteal, and femoral arteries, to the arteries of the forearm and leg in amputations, and to the arteries after removal of the breast, and no case of secondary hemorrhage has followed its use. In one instance in my own practice secondary hemorrhage followed torsion of the interosseous artery, and a similar misfortune happened recently to another surgeon in this city; but in both cases there had evidently been some defect in the method of application. In the same period, in that hospital, two fatal cases of secondary hemorrhage followed the use of the ligature,—in one from the axillary artery after amputation at the shoulder for injury, in the other after disarticulation at the hip for disease.

The following table, collated by Prof. Murdoch, of Pittsburg, from the records of the Western Pennsylvania Hospital,[1] exhibits the frequency with which torsion has been employed in that institution for the control of hemorrhage from large arteries. It includes cases at every period of life, from early childhood to advanced age.

Femoral	95 times.
Popliteal	14 "
Axillary	15 "
Anterior tibial	276 "
Posterior tibial	276 "
Brachial	62 "
Radial	40 "
Ulnar	40 "
Total	818 times.

Torsion is a very simple operation, requiring no special instruments for its performance other than the strong serrated (not toothed) artery-forceps carried by every surgeon. The ends of the divided artery should be caught in the jaws of the forceps, and the vessel drawn gently from its sheath, and twisted or rotated on its long axis until the feeling of resistance is overcome: five or six turns are usually sufficient. The brittle internal and middle tunics of the vessel break, curl up, and reduplicate themselves, forming a valve-like plug, while the elastic external coat twisted into a ball gives additional support. A firm clot forms within the vessel, and an exudation of plastic lymph cements the reduplicated tunics and renders the lumen of the artery impervious. Organization of the lymph soon follows, and all the structures are thus bound together in the cicatrix.

---

[1] Chicago Medical Journal and Examiner, June, 1889.

Easily and rapidly performed, torsion seems to be more absolutely safe than the ligature. The twisted ends of the vessel are not devitalized, and hence no dead tissue is left in the wound to slough or decompose, no foreign body to irritate, and no ligature to loosen, ulcerate, or slip. It is difficult to conceive of the necessity of any other method of controlling hemorrhage in the wounds of children, except in punctured wounds of large arteries, where both distal and proximal ends of the vessel must be dealt with; ligature is then the simpler and more convenient method.

The Ligature.—The ligature is a safe and efficient means of permanently controlling hemorrhage, but it is open to the objection that, no matter how carefully it may be applied, a foreign body is left in the wound, and the vitality of that portion of the ligated vessel which projects beyond the point of ligature is destroyed. A limited necrosis must result; the dangers of septic contamination are therefore greatly increased, and, unless careful antisepsis is observed, disaster is liable to follow.

Ligature of a bleeding vessel is accomplished by grasping its severed end with forceps and gently drawing it out from its sheath, so as to free it from the surrounding structures; the ligature is then thrown around the vessel close to the sheath, and tied with a single *reef* or *sailor's knot*, which is drawn tightly enough merely to divide the internal and middle tunics of the artery, without inflicting too great damage upon the external tunic. Both ends of the ligature are now cut short, and the ligated vessel is allowed to retract within its sheath. When bleeding from a number of small vessels situated close together persists, it is better to include them all in a single ligation than to waste time and blood in an effort to isolate each vessel.

The materials employed for the ligature of vessels are the same as those used for sutures, and the same scrupulous care should be taken to render them aseptic. Too great vigilance cannot be observed in this matter. Fine hard-twisted carbolized sewing-silk probably possesses as much merit as any other substance, and can always be obtained. Catgut, if properly prepared, is quite reliable, and is in time absorbed by the tissues. Greater care is required in tightening the knot, however, and the second turn of the knot should be reinforced by a third turn, as a guard against slipping of the ligature.

Pressure is useful as a temporary means of controlling hemorrhage, but it must be used cautiously, lest serious damage be inflicted upon uninjured parts. It should always be applied directly to the bleeding point, and not to the limb above the seat of injury, except during an operation, and must be removed as soon as other and more efficient measures can be employed. As a method of permanently controlling hemorrhage it is very unreliable and likely to end in failure. The practice of encircling a limb by a tourniquet to arrest bleeding is an exceedingly dangerous one, and in three cases of which I have personal knowledge it was the direct cause of death, by producing gangrene in the limb. It should never be employed except during the performance of an operation.

Styptics are seldom required for the arrest of hemorrhage, and their use cannot be too strongly condemned. Unfortunately, it is the custom with some practitioners to resort to styptics in every case of active bleeding, and the wounds which fall into their hands are systematically daubed or tightly crammed with some styptic, most commonly the solution of the subsulphate or perchloride of iron. It is true that this treatment will arrest hemorrhage in many cases, though *not in all;* but, in doing so, it so irritates and befouls the wound that union by primary adhesion or "first intention" is absolutely impossible. Unreliable and unsafe, the use of styptics renders a clean cut surface unfit for rapid repair, adds to danger and suffering, and retards recovery. It is a practice dictated by timidity and ignorance, and ought to be abandoned altogether.

Cleansing the Wound.—The skin in the neighborhood of the wound must be well washed with soap-and-water and afterwards with water holding some germicide in solution, preferably the one to one-thousand solution of corrosive sublimate, thrown from a syringe or squeezed from a sponge or a pledget of antiseptic cotton. All foreign bodies—fragments of wood, glass, iron, etc.—and clots of blood must be carefully removed from the wound, either by picking them out with clean forceps or by washing them away with a stream of antiseptic fluid.

Drainage.—No part of the treatment can ever be more important than that which provides for the escape of the putrescible animal fluids discharged by the wound itself. Unless free outlet is left for the escape of these fluids (blood, serum, etc.), they accumulate in the wound, force its surfaces asunder, defeat repair, and increase the danger of septic absorption. Drainage may be attained by counter-openings, tents, setons, and the like, but is best accomplished by the insertion of perforated tubes of glass, decalcified bone, or the common black-rubber tubing, into the cavity of the wound, through its most dependent angle. The ends of the tubes should be allowed to project a short distance beyond the level of the skin and be held in place by aseptic safety-pins. Wounds of slight extent require only provision for the escape of the serum, and efficient drainage may be secured by the introduction of a few strands of carbolized silk, catgut, or horse-hair. Openings must always be cut in the first layer of the dressing, to free the projecting ends of the drain from pressure and consequent obstruction. No invariable rule can be laid down for the removal of the tubes; they should be withdrawn when there is no longer a discharge to be drained away,—usually not sooner than forty-eight hours; but it is better to allow them to remain longer than is absolutely necessary than to remove them too soon.

Closure of the Wound.—It is necessary for the perfect repair of a wound that its surfaces shall be placed in exact contact as soon as possible after its infliction. This object is effected by various measures,—

viz., sutures, adhesive plaster, compresses, and bandages. Simple incised wounds of limited extent usually require no other treatment than to arrest the bleeding and to bring the edges together and retain them by a few strips of adhesive plaster firmly drawn, supplemented by an absorbent compress and bandage. The divided parts adhere promptly, organization follows, and the surfaces are quickly joined together by a living bond of union.

In more extensive wounds the tendency of the divided parts to separate must be overcome by more effectual mechanical measures. It is not sufficient to retain the edges in contact; the deeper parts must be kept in apposition until organization can take place throughout the adhesive lymph which cements them together. This can be accomplished only by deep or "buried" and superficial sutures, aided, as already advised, by compresses and bandages.

Sutures.—The materials usually selected for sutures are silk, catgut, horse-hair, silver wire, or "silk-worm-gut." Pure well-annealed silver wire, as fine as possible (No. 28 to No. 30), possesses decided advantages over other sutures. It is strong, pliable, easily introduced, readily tightened by two or three turns, affords perfect support to the wound without constriction, is not absorbable, can be adjusted and readjusted in closing the wound, and if accidentally drawn too tight can readily be relaxed by untwisting a turn or two or by cutting it between the first turn and the skin. When this is necessary, the constriction is at once relaxed, and the hook-like form of the suture still affords support to the edges of the wound. Sutures of silver may be left for an indefinite period without causing irritation. Horse-hair possesses similar advantages in a less degree. It is very easily introduced, but is a little difficult to tie, and is not strong enough for use in large wounds unless doubled. In wounds of the eyebrows and eyelids, and in plastic operations generally, it is an excellent suture. Silk sutures are easily introduced, and afford abundant support to the edges of the wound; but, unless thoroughly aseptic, they are irritating, and, if retained long, act as setons; if drawn tightly, they constrict and strangulate the edges and cut their way out. The very best quality of finely-twisted or braided silk must be selected, and may be rendered perfectly aseptic by boiling for thirty minutes in a five-per-cent. solution of pure carbolic acid. It may be kept for an indefinite period in the same solution, or in alcohol or carbolized oil (five per cent.). Catgut is a favorite suture with many surgeons, but really possesses no advantages over carbolized silk. If not properly prepared, it is unreliable, and, owing to the difficulty of sterilizing it perfectly, it is not free from the dangers of conveying infection. Volkmann reports a case of anthrax clearly traceable to its use. Silk-worm-gut makes an excellent suture, but is unabsorbable, and remains unchanged in the tissues for many months.

For the introduction of sutures, a straight needle, somewhat spear-pointed, and having a large *countersunk eye*, is the easiest to use and the most generally serviceable. In wounds of the cheeks and eyelids fine curved needles are required to surmount the irregular contour of the surface.

Sutures are applied in various forms,—viz., the interrupted, the continuous, the twisted, and the quilled. The interrupted is the form most generally used, and for nearly all purposes is the best. The stitches are introduced at short intervals, so as to hold the edges of the wound together at many separate points. The first suture should be placed at the middle, the others alternately on one side or the other of this one until the wound is closed. Each suture must be carefully adjusted so as to hold the edges in exact contact, without inversion or eversion of the skin, and without constricting any portion of the tissues encircled by the loop. "One suture too tightly drawn may result in the death of the patient." (Esmarch.)

In deep wounds with division of muscles, as in the face, superficial sutures are not sufficient, and the advice of Mr. Keetly should be followed, "to bring all the severed parts together by means of *buried* aseptic sutures." Chromicized catgut, carbolized silk or silk-worm-gut answers best for this purpose. This measure secures perfect contact of the entire surface of the wound, and more speedy union. As a general rule, strips of adhesive plaster should not be employed to support the sutures, and when resorted to should be always applied over aseptic compresses placed on each side of the wound. When applied directly to the skin they cause irritation, become foul, and interfere with drainage.

The continued suture is inserted in an uninterrupted seam, in the manner employed by glovers and seamstresses. It secures close apposition of the edges and is a good suture, but in large wounds must always be supplemented by very free drainage. This form of suture is especially applicable in wounds of the intestines, carbolized silk and chromicized catgut being the materials best suited for use.

The twisted suture is usually employed in plastic operations where support and moderate pressure are required, as in hare-lip and deep wounds of the face; it is clumsy at best, is extremely liable to become foul from absorbed discharges, and certainly has no advantages over the interrupted silver-wire suture.

External Dressing.—Having secured coaptation of the surfaces of the wound, and ascertained that the drainage is perfect by passing a stream of antiseptic fluid through the tubes, the external dressings must be applied. These dressings must be absorbent, germ-destructive, and so adjusted as to sterilize the air as it comes in contact with the discharges, to exert accurate and continuous pressure upon the sides of the wound, and to retain the affected part in a state of absolute rest. The wound is first rendered sterile by the means detailed; its discharges must be prevented from decomposing by being strained through an antiseptic covering, and the wound itself hermetically closed. The edges should first be well dusted with iodoform or powdered boric acid, so as to sterilize the discharge by bringing it in contact with a germicide as soon as it escapes. The impervious strip of protective material formerly deemed essential may be safely discarded, and its place supplied by a loose layer of moist iodoform or carbolized gauze, perforated for the ends of the drainage-tubes. External to this several layers of sublimate gauze must be arranged so as to exert a moderate degree of pressure and at the same time absorb the discharges from the drainage-tubes. A thick layer of borated cotton or of salicylic wool surrounds all, and is retained in position by an accurately and snugly applied roller bandage. If, in spite of deep or buried sutures, there be much tendency to separation of the deeper portions, aseptic pads should be applied on each side, and held in position by soft absorbent bandages. "This keeps the parts mechanically together, prevents nerve-tension, and promotes absorption." (Gamgee.)

No impervious material for the external dressing is required. When an extremity is involved, a light splint should be adjusted to it, and the part elevated, so as to prevent all motion in the damaged tissues, to secure absolute rest, and to avoid venous engorgement. This dressing ought not to be disturbed for several days, unless the wound becomes hot and painful, the child feverish and restless, and the dressing soiled with offensive discharges. Usually the dressing remains dry or but slightly soiled, the pulse and temperature are but little affected, and there is no pain. A wound in such a state should not be touched; nothing can be gained by removing the dressing and inspecting the parts, the child is only subjected to unnecessary pain, and the wound-surfaces are disturbed injuriously. The less it is interfered with, the more rapid and perfect will be the repair. When it becomes proper to remove the first dressing, it should be well moistened with an antiseptic lotion and cut layer by layer with scissors, and then gently lifted from the wound; the skin should be well washed, the drainage-tubes shortened or withdrawn, the stitches removed, and a new dressing in every way similar to the first applied.

If the surgeon does not have at his command all the elegant and expensive appliances for the antiseptic dressing of a wound, he will be obliged to improvise them from whatever crude materials he can find within reach. Strips or shreds of clean old linen or muslin are soft, pliable, and chemically pure, and will absorb fluids rapidly. Such materials placed for a few minutes in some hot antiseptic solution—as the solution of corrosive sublimate, one part to one thousand (made by dissolving seven and a half grains of the sublimate with an equal quantity of common salt in one pint of water), tincture of iodine in water, one to one hundred and fifty, carbolic acid in water, one to twenty, or a saturated solution of boric acid in hot water—will be transformed into a very perfect antiseptic dressing, from which pads, compresses, and bandages can readily be made. Silk, linen, or cotton thread similarly treated is rendered perfectly innocuous, and affords material for sutures and ligatures which is just as reliable as the most expensive that can be purchased from the dealers. A skein of this thread inserted into the wound, in the absence of the perforated tubes, secures good drainage. The wound, properly cleansed with a portion of the same solution that has been used to render the dressing antiseptic, may now be closed and dressed with these improvised materials, and repair will go on just as rapidly and perfectly as it does under the most complicated dressings.

After-Treatment.—If properly applied, the first dressing is very often the only one required; the exposed surfaces of the wound unite without febrile excitement or systemic disturbance and without sufficient discharge to soil the dressing. The union, however, is not yet firm, and compresses and bandages will be required for several days to give support to the newly-formed tissues. Removal of the sutures will depend upon the progress of repair; they should be withdrawn as soon as possible,—usually in from forty-eight to seventy-two hours, but in large wounds, with tendency of the edges to separate, they should not be disturbed for several days; time must be allowed for deep cicatrization to occur before their support can be dispensed with. If any of them are too tightly drawn, or show a tendency to cut out, they should be removed at once, as they only cause irritation and endanger repair in other parts of the wound. They are best removed by grasping them gently at the twist or knot with a pair of forceps, dividing them with scissors, and withdrawing them carefully, so as not to put any strain upon the wound. Metallic sutures must be cut close to the skin, and the hook-shaped ends straightened before attempting to remove them. Withdrawal of the sutures must always be followed by the support of compresses and bandages, and these must be employed until everything has consolidated.

Ordinarily very little treatment is required beyond the occasional adjustment of dressings and bandages, to keep the parts at rest until nature completes the reparative process. If, however, a portion of the wound fails to unite or breaks down before union is perfect, additional care must be exerted to keep the parts aseptic until healing by granulation occurs. If the parts become hot and painful and the child feverish, the dressing must be removed, the sutures taken out, and the source of irritation sought for and removed. If discharges have been retained, provision must be made for their escape, and it may be proper to substitute cool or antiseptic irrigation for the dry dressing heretofore employed.

Attention to the hygienic surroundings of the child will also be necessary. The diet should be bland, nutritious, and easily digested; broths, milk, etc., should be given generously from the first, and later may be reinforced by wine and more substantial food. The child should be kept, if possible, in an airy, well-lighted, and well-ventilated upper room; the bed, bedclothing, and garments worn must be clean, and should be cleansed frequently. It is true that children living on impure and insufficient food, and breathing a foul animalized atmosphere, recover well from severe injuries; but it is equally true that they do infinitely better when surrounded by proper hygienic conditions.

CONTUSED AND LACERATED WOUNDS.

A contused wound is inflicted by a blow from a blunt instrument or missile, as a club or stone, or the toe or heel of a heavy boot, or is caused by a fall in which the brow or face strikes against a curbstone. The edges of the wound are inverted, abraded, and greatly ecchymosed, and the vitality of the tissues is seriously impaired, often far beyond the apparent limits of the injury.

Lacerated wounds present many of the features of contused wounds, and the two forms of injury may properly be considered together. In them the "tissues are both bruised and torn," and the edges are inverted, irregular, and often darkly discolored. The skin is torn from the underlying fascia, and hangs limp and loose, having lost its elasticity by the stretching to which it has been subjected; in severe injuries the underlying fascia is torn to shreds, and the muscles are disintegrated and reduced to a pulp. Such injuries are commonly caused by machinery, by railway accidents, or by the passage of a carriage- or wagon-wheel over the body. In adults they are very often followed by more or less sloughing of the damaged tissues. In childhood this result is scarcely to be feared unless the entire vascular and nervous supply of the part has been destroyed.

Hemorrhage.—The hemorrhage caused by contused or lacerated wounds is usually trifling, except when large arterial and venous trunks are severed. Even then there is no active hemorrhage beyond the momentary gush of blood which immediately follows the accident. I have several times seen the torn end of the brachial artery so effectually closed by a clot that not a drop of blood escaped from it, although the arm had been torn from the body just below the shoulder and the artery hung loose amid the mangled tissues of the stump. The violence which severs the vessels lacerates and contuses the internal and middle tunics, and thus favors the rapid formation of a clot; the clot is temporary, but it effectually prevents any further bleeding. A troublesome oozing, however, not unfrequently comes from the surface of the wound, and, while the quantity of blood lost may not be great, its continued escape increases and prolongs the shock.

Pain.—The pain of contused and lacerated wounds is not usually severe; the tissues are benumbed by the bruising force of the accident, and a child suffering from a crush of a limb severe enough to necessitate amputation rarely makes much outcry if the injured parts are not disturbed. Laceration and contusion of the toes and fingers are excessively painful, however, and such injuries are not unfrequently followed by tetanus.

The constitutional effects may be so mild as to merit little attention, or so severe as to imperil the life of the child.

Shock.—The shock which follows severe wounds of this character is always very profound, and death may result from syncope or asthenia. When reaction occurs it is usually prompt, and is sometimes attended by undue febrile excitement, with mild nocturnal delirium. The wound during this period becomes painful, hot, and swollen, and a copious sanious discharge escapes from it. The surrounding skin becomes tumid, and sometimes is covered by bullæ filled with a blood-stained serum. This period is usually short, and is succeeded by a rapid subsidence of all alarming symptoms; the pulse and temperature fall, the skin becomes cool and moist, and the wound assumes a healthy appearance. If proper care be observed in the primary dressing, this febrile state can in great measure be averted.

Complications.—Since the structures in the vicinity of the wound are always injured, and sometimes so seriously that their vitality cannot be restored, necrosis results, and sloughing of the damaged parts must precede repair. In many cases of extensive injury the disintegrated textures perish over a wide area by a localized gangrene. The dead skin, at first dark purple in color, becomes ashy gray or brown; an active cell-infiltration and the development of young granulation-tissue follows in the borders of the living skin; and the dead tissues separate slowly from the living, and leave a granulating surface underneath. Unless perfect antisepsis is maintained, suppuration, often dangerous and exhausting, is very liable to occur. The danger of septic infection is, fortunately, not great in childhood; but it is, nevertheless, important to protect the wound from all sources of contamination and to keep it pure. Putrefaction of the discharges, and the consequent formation of irritating and poisonous alkaloidal products of decomposition in the wound, are prevented by this care, and physiological repair by granulation goes on uninterruptedly.

TREATMENT.

The treatment of contused and lacerated wounds differs from that adapted to the simpler forms. The tissues have been subjected to greater violence, a wider area has been severely damaged, and important textural changes, limited necrosis, and sloughing are often unavoidable. Union by granulation is the only method of repair usually attainable, and the prevention of septic infection becomes of paramount importance. But in superficial wounds, whether contused or lacerated, especially in wounds of the scalp or face, healing by first intention is possible, and an effort should always be made to secure it.

The indications for treatment, accordingly, are not only to stop bleeding, to cleanse, close, and drain the wound, and to apply external dressings, but also to preserve the vitality of all tissues not hopelessly damaged, to hasten the separation of disintegrated and dead tissues from the living, and to prevent the occurrence of decomposition and suppuration by adherence to a rigid antisepsis.

The hemorrhage having been controlled by the measures detailed under Incised Wounds, and the skin carefully washed with soap-and-water and afterwards with some antiseptic solution, the wound should be thoroughly cleansed and freed from all foreign bodies.

Great care must be taken to bring the antiseptic fluids in contact with the whole surface, by inserting the nozzle of the syringe or irrigator underneath the flaps of loose integument; but the utmost gentleness must be observed in handling the damaged tissues.

The surgeon should hesitate to clip any loose shreds of skin not absolutely detached from the wound: it is better practice to cleanse them carefully and replace them as nearly as possible in their former position. Vitality is sometimes preserved in very doubtful-looking tissues, with a corresponding decrease in the size of the scar. In wounds of the hand this precaution should be strictly observed: extensive and hopeless-looking crushes of the hand and fingers are sometimes repaired in a remarkably perfect manner, and, no matter how unshapely and imperfect the condition of the member may be, no artificial substitute can ever equal it in value.

Closure of the Wound.—If the wound be slight or situated in the scalp or face, its edges must now be united by a few points of interrupted suture, a protective dressing applied, and the wound treated as an incised wound. Where the injury has involved a wider extent of tissue, with laceration of the skin, fascia, and muscles, no attempt should be made to close the wound tightly. A few points of interrupted suture may be inserted to lessen the separation of the skin and to give temporary support to the torn muscles, but they must not be drawn tightly nor placed so close together as to interfere with free drainage. As a general rule, adhesive plaster should be avoided.

Drainage.—The introduction of drainage-tubes for the discharge of the wound-secretions will generally be required, and if necessary counter-openings should be made at the most dependent part. In extensive wounds the drainage-tubes should be of large size, not less than one-third of an inch in diameter.

External Dressing.—When the wound has been thoroughly cleansed with the antiseptic lotion, and sutures and drainage-tubes inserted at the points deemed necessary, it is ready for the external dressing. The whole surface should now be dusted with powdered iodoform and covered by a few layers of iodoform or carbolized gauze through which openings have been cut for the ends of the drainage-tubes. Several layers of moist sublimate gauze are now applied to cover the entire area of the wound and the skin for some distance beyond its margins. A thick layer of borated cotton or salicylated wool is placed outside of all and held in position by a carefully-adjusted roller bandage. The utmost care must be observed to avoid constriction of the wounded parts, especially in the extremities, lest the feeble circulation be still further impeded and gangrene be induced. The dressing must be so adjusted as to support and protect the wound and keep it at perfect rest. The moderate elastic compression afforded by the external layer of cotton wool is highly beneficial by retaining its surfaces in contact; but beyond this all pressure and all tight bandaging are mischievous and injurious.

After the dressing is completed the wounded extremity should be slightly elevated by placing it upon a pillow, and dry warmth by hot bricks or bottles of hot water will be required when the vitality of the part is low. A light splint is useful by affording additional support. No further interference will be needed until after a period of forty-eight hours, unless the dressings become foul with the discharges, the child be restless and sick, the wound painful, or the temperature elevated above 101° F. Usually at the end of forty-eight hours the first dressing should be removed and the wound dressed again. If its appearance is satisfactory and there is no sign of suppuration or extensive death of tissue, the sutures may generally be removed, the drainage-tubes should be examined, readjusted, or removed, the surface of the wound again lightly dusted with iodoform, and the new dressing applied at once with the same rigid antiseptic care as was observed in the primary dressing. It should not again be disturbed for several days, unless febrile symptoms arise or the dressing becomes foul. Frequent dressings certainly retard the healing process.

If, however, the wound is hot and painful, its edges swollen and everted, its surface covered with ashy-gray sloughs, the discharge profuse and ichorous, and the child feverish and sick, the wound is no longer aseptic, it is practically a phlegmon, and repair without more or less extensive suppuration and sloughing becomes impossible, unless some other and more efficient method of treatment is employed. Warmth and moisture are now required. A water dressing by fomentations or by continuous irrigation with cool or tepid antiseptic solutions must be substituted for the dry antiseptic dressing. The advantages of this change consist in the prevention of decomposition of the necrosed parts, the continuous removal of irritating discharges, and the more speedy separation of the dead tissues; primary adhesion has failed, and it becomes necessary to "encourage the process of sloughing in order to bring into operation that of healing by granulation." (Gant.)

In those very severe wounds which occasionally involve the extremities and in which no hope of repair without great loss of substance can be entertained, the *continuous local bath* by immersion of the wounded part in a vessel filled with tepid water rendered antiseptic by the addition of corrosive sublimate (one to five thousand), or carbolic, boric, or salicylic acid, possesses many advantages over other methods of treatment.

The apparatus required for the continuous local bath is a box or tub of tin or zinc, which can be placed at the foot or side of the bed by cutting away one or more of the slats. The outer edges of this tub are provided with hooks, from which a sling of muslin is suspended across the cavity of the tub, and upon this sling the injured extremity must rest while immersed in the antiseptic solution. The temperature of the solution may be kept up by means of a spirit-lamp placed underneath the tub. The continuous bath should not be employed, however, immediately after the injury. The recently-injured tissues commonly require the influence of dry heat rather than of moist, and hence they should first receive the benefit of a dry antiseptic dressing, with dry heat and moderate elevation of the limb, until the structures not hopelessly damaged have recovered their vitality and some degree of cellular proliferation is present in the wound; otherwise the little life remaining may be destroyed through vascular disturbances induced by the too early application of an unusual degree of moisture. It is a method of great value in cases of deep sloughing and progressive suppuration with burrowing of pus beneath the muscles and fascia. The limb is placed in water at a temperature regulated by the sensations of the patient, and must be kept in this bath for a week or longer, until all the sloughs have separated. The water in this bath must be kept fresh and pure by frequent changes, and its temperature may be elevated gradually, so as to hasten the separation of the sloughs. The limb usually swells enormously and becomes discolored from imbibition of fluid, and the granulations are blue-looking and œdematous; but this discoloration and œdema disappear when it is removed from the bath, the granulations soon regain their natural appearance, and cicatrization is completed in the same way as in ordinary granulating wounds.

Occasionally, despite the utmost care, the granulations become pale and unhealthy or florid and exuberant, and cicatrization ceases. Wounds in this condition require the application of stimulating lotions to rouse the feeble granulations to a healthy activity or to repress the inordinate vascularity which delays the completion of the healing process. Weak astringent lotions, as the solution of sulphate or chloride of zinc, or dilute nitric acid, become valuable adjuvants to treatment: where a more positive impression is desired, the solid nitrate of silver brushed lightly over the surface of the wound will be useful in hastening "desiccation." The oxide-of-zinc ointment, rendered aseptic by the addition of boric or carbolic acid, is sometimes useful in hastening cicatrization; but, as a rule, salves and ointments may be very generally discarded.

PUNCTURED WOUNDS.

A punctured wound is an injury inflicted by a sharp- or dull-pointed instrument or body, as a nail, a fragment of iron, of wood, or of bone, a thorn, the tooth of an animal, or the slender blade of a knife. Its depth far exceeds the extent of the external injury or visible lesion, and its character will vary with the form and nature of the vulnerating body. A puncture with the sharp blade of a knife causes a deep incised wound, while that caused by a nail or a thorn is both contused and lacerated.

Punctured wounds acquire importance from their depth, their locality, and the nature of the structures injured. If the skin and subcutaneous fat alone are punctured by a clean instrument, no serious consequences are likely to follow, and the wound will heal kindly and without suppuration under a simple antiseptic dressing. If, however, the weapon penetrates a joint or wounds a large arterial trunk, the consequences will be of a very serious character,—a violent traumatic synovitis in the one case, a fatal hemorrhage or a diffused traumatic aneurism in the other.

But if the wound is caused by a rough-pointed instrument, as when a rusty nail or a fragment of wood or of iron penetrates the skin, muscles, and fascia, it is deep, lacerated, and liable to become poisoned, either by the puncturing body or by foreign or septic matter conveyed from the skin to the bottom of the wound.

Drainage of such an injury is very difficult to secure, and decomposition of the retained extravasation, with violent and destructive inflammation and widely-diffused suppuration, is almost certain to follow. Accidents of this character involving the palms of the hands or the soles of the feet are always liable to be followed by most serious consequences, among which tetanus and general blood-infection are not rare. Such injuries require prompt and careful treatment. If the puncture has been inflicted by a blunt body, as a rusty nail, the wound should at once be freely incised, so as to give abundant room for the escape of blood and extravasated fluids, its entire surface should be thoroughly cleansed and irrigated by some efficient antiseptic fluid, as the corrosive-sublimate solution, one to five hundred, a drainage-tube inserted, and an antiseptic dressing applied. Where the wound is so located as to permit it, the part should be immersed in the antiseptic for an hour or two, and then cauterized with pure carbolic acid before the application of the primary dressing.

In treating bites of animals, the method pursued at Bellevue Hospital, New York, is to immerse the bitten part in a hot solution of bichloride of mercury, one to two hundred, for thirty minutes, then to cauterize the wound freely with fuming nitric acid, and afterwards to dress it antiseptically.

If the wound has been neglected, it must be incised freely upon the first evidence of inflammation in the part, and a careful search made for foreign bodies, while counter-openings must also be made if needed to secure free drainage.

Wounds involving joints require a rigid antisepsis, with extension and fixation of the joints, and the external application of cold by ice-bags, cold compresses, and the like.

When a large artery has been punctured, clearly the safest practice is to enlarge the external wound and secure the vessel by ligatures applied to both proximal and distal sides of the puncture, and then to divide the vessel entirely between the ligatures. Such wounds are always attended by danger, and require energetic treatment from the moment of accident. It is useless to temporize with them: valuable time is wasted and the life of the patient may be sacrificed by hesitating. No punctured wound should ever be regarded as trivial, and certainly no other form of wound requires more careful management.

POISONED WOUNDS.

When certain specific emanations from living or dead animal bodies are introduced into wounds, whatever their form may be, they acquire new and deadly qualities, and the traumatism sinks into insignificance in the presence of a poison "acting upon the blood, contaminating the constitution, and developing distinct and special symptoms." (Poland.)

The sources of wound-contamination are varied, but may be classified as follows: first, the poisonous secretions from healthy but venomous reptiles or insects (bites of serpents, stings of bees, etc.); second, the discharges from diseased animals (glanders, hydrophobia, etc.); third, fluids from recently-dead animal bodies (dissection-wounds, etc.). The poison (or poisons, for they are probably numerous) from dead animal bodies undoubtedly belong to the alkaloidal products of decomposition, the *ptomaines* or *cadaveric alkaloids*, which in their action upon the animal economy resemble several of the poisonous vegetable alkaloids. That present in the venom of reptiles and poisonous insects probably belongs to the same class of animal poisons,—the poisonous agent being a chemical product, incapable of multiplying in the blood, requiring no period of incubation, not transmissible to other persons, and exerting its toxic power in proportion to the amount absorbed. On the other hand, inoculation by the discharge from diseased animals—from a dog suffering with hydrophobia, or from a horse afflicted with glanders—depends upon the introduction of specific germs into the bite, or at least a virus, which contaminates not only the wound, but also the blood of the individual. The disease acquired by inoculation may be transmitted from one individual to another, and after death the blood teems with micro-organisms. The smallest quantity inoculated is sufficient to produce all the characteristic effects, but the outbreak does not occur until after a period of incubation or quiescence, during which the germs multiply and acquire destructive energy.

POISONED WOUNDS RESULTING FROM STINGS OF INSECTS, BITES OF SERPENTS, ETC.

The stings of insects—bees, wasps, and the like—although very painful, usually require very little attention. The pain is promptly allayed by bathing the part with a solution of soda or ammonia, or by covering it with olive oil, and the swelling disappears in a few hours. If, however, a young child is stung simultaneously in many places, as sometimes happens during the swarming of bees, the severity of the pain and the quantity of poison introduced into the blood produce an alarming degree of constitutional disturbance, and death occasionally results. Stings involving the tongue and fauces are followed by great swelling of the parts, and death may speedily follow from œdema of the glottis. Such cases are best treated by alkaline gargles and washes, but, if symptoms of suffocation occur, free scarification of the glottis becomes necessary, and tracheotomy may be demanded to save life.

The sting which conveys the poison is a slender, barbed, needle-like weapon, which is often left in the skin, and, as its presence is a source of irritation, it should be grasped with fine forceps and removed; afterwards the part should be bathed with a solution of soda or carbolized oil. The alarming depression which occasionally follows multiple stings is best combated by diffusible stimulants, brandy, ammonia, etc.

In the southern and southwestern parts of the United States, the wounds inflicted by the mandible of the tarantula and the centipede and the stings of the scorpion are said to be be followed by serious local inflammation and sometimes by violent constitutional disturbance. Dr. Linceium, of Texas, reports the case of a child four years old who died in six hours after the bite of a very large centipede. Dr. Thomas A. Pope, also of Texas, reports a death from a tarantula-bite; the man was bitten in the neck, and died from asphyxia due to the swelling.[1] In southern Italy and in the Orient death is said occasionally to follow the sting of the scorpion. The treatment consists in neutralizing the local effects of the poison by alkaline washes and in combating the constitutional depression by diffusible stimulants.

The bites of poisonous serpents constitute a very serious class of injuries; the bites of the cobra, duboia, and other reptiles in India are rapidly followed by death. In the United States the only poisonous serpents are the rattlesnake, the copperhead, and the moccasin-snake, the latter found only in the Gulf States. The bites of the rattlesnake and the copperhead are very similar in their effects, both being followed by an alarming train of symptoms, which not uncommonly end in death.

The venom of all serpents is secreted by a pair of glands situated on either side of the upper jaw below the eyes, which communicate with a groove or tube in the fangs. The fangs are movable, very sharp, grooved or channelled for the transmission of the venom, and in their quiescent state lie in folds of the mucous membrane lining the roof of the mouth. When the serpent strikes, the muscles attached to the base of the fangs contract and throw them into an erect position, and compress the glands or poison-sacs simultaneously, injecting the venom along the grooves when the fangs are driven into the flesh of the bitten animal.

The venom is a yellowish-green, albuminous fluid, acid in reaction, with a specific gravity of 1.044, and, according to Mitchell and Reichert, contains three proteid substances,—venom-globulin, venom-peptone, and venom-albumen.[2] It is not affected by heat, cold, acids, alkalies, or decomposition, may be taken into the stomach with impunity, and does not render the flesh of animals destroyed by it unfit for food.

Symptoms.—The wounds inflicted by all venomous serpents are speedily followed by pain of an intense character, and by rapid swelling and discoloration of the parts. The swelling extends rapidly towards the trunk; the skin is livid, mottled, and sometimes vesicated; in severe cases the subcutaneous connective tissue is infiltrated with an ichorous, offensive fluid like that of gangrene, and the wound itself may become gangrenous.

[2] Philadelphia Medical News, 1883; Lancet, July 21, 1883.

Severe constitutional symptoms, manifested by intense shock, tremor, dizziness, nausea, and vomiting, with feeble, irregular heart-action, appear very early. In fatal cases death may occur in a few hours or may be delayed for several days, and may result from either heart-failure or coma, or may be preceded by the typhoid state or by symptoms of a septic character, with delirium, convulsions, and coma. The condition of the reptile at the time the bite is inflicted, the age and health of the person bitten, and the quantity of venom injected into the tissues, undoubtedly influence the result. The bite of a full-grown, active serpent that has not recently bitten any other animal will be followed almost instantly by extremely violent symptoms even in a vigorous person of adult age, and possibly by death; whereas a similar bite inflicted after the serpent has bitten several animals will be followed by comparatively mild symptoms. The poison of all venomous serpents—except possibly that of the cobra, whose victims die too promptly to permit such a change—destroys the coagulability of the blood and disintegrates its red corpuscles; hence the chief post-mortem appearances are a fluid condition of the blood, and extravasations and sanguinolent effusions into the serous cavities.

Treatment.—As there seems to be no absolutely reliable antidote for the venom, the treatment of serpent-bites must aim to prevent the entrance of the poison into the blood, and to overcome the depression of all the vital functions which follows its absorption even in small quantity. The first object is best accomplished by immediately applying a very firmly drawn ligature to the bitten extremity some distance above the wound, so as to stop all circulation in the part, and then by encouraging the wound to bleed by freely incising it and employing active suction with the lips, or preferably with a cupping-glass, if one can be obtained, for there is always danger that the venom may poison an unobserved abrasion on the lips. The wound must then be washed freely with diluted aqua ammoniæ or diluted tincture of iodine. Recently a five-per-cent. solution of potassium permanganate in water is recommended by Dr. Lacerda Filho[1] and by Mr. V. Richards,[2] either locally applied to the wound or injected underneath the contiguous skin. It is asserted to have effectually neutralized the cobra-poison. If the bite is on the face, cauterization with a hot iron is recommended before using the permanganate lotion, and certainly will be effectual.

If the patient survives, more or less sloughing of the skin and subcutaneous connective tissue may be expected, and this should be favored by free incisions and by warm detergent irrigations. Constitutional depression is best met by moderate doses of morphine to relieve the pain (and terror), and by the free administration of alcoholic stimulants in the form of whiskey or brandy. These should be given, not in moderate but in very large doses, until signs of intoxication are unmistakable; after this the patient should be kept mildly under the influence of the stimulant until danger is past. The quantity of whiskey or brandy required to produce intoxication in men suffering from the bite of the rattlesnake is stated to be enormous; and the late Surgeon G. E. Cooper, U.S.A.,[1] reports one instance in which a bottle of brandy and a bottle and a half of whiskey were drunk before any effects were observed. It is asserted that as soon as intoxication occurs the muscular tremors stop in the bitten limb and the swelling ceases. Children are usually very susceptible to alcohol, and care must be observed in its use, lest the depression of large doses intensify the effects of the animal poison.

WOUNDS POISONED BY CONTACT WITH THE SECRETIONS FROM DISEASED ANIMALS.

HYDROPHOBIA (RABIES CANINA, LYSSA, HUNDSWUTH).—This fearful malady originating in the canine race is communicable to man and to all warm-blooded animals by inoculation with a specific virus present in the saliva and blood of the rabid animal. The common source of inoculation is the bite of an infected dog, but the bite of the rabid wolf, fox, or badger is no less dangerous, and it is stated by General Dodge, U.S.A.,[2] that in the valley of the Republican River, Colorado, the bite of the skunk is almost invariably followed by hydrophobia. Rabies is not transmissible from man to man, nor from man to the dog. Pasteur has produced rabies in healthy animals by inoculating them with the cerebro-spinal fluid and brain-substance of animals recently dead of the malady.

Inoculation may occur through trifling abrasions on the hands or face if in any way brought in contact with the saliva of a rabid animal; even the bite of an apparently healthy dog has been followed by rabies. The virus is also communicable by the blood of a rabid animal. A student, while examining the body of a dog that had died from rabies, accidentally inoculated himself by wounding his finger, and died six weeks afterwards from hydrophobia. (Hertwig, Van Buren.)

Fortunately, about one-half of the persons bitten by rabid animals escape infection; but bites upon unprotected portions of the body are extremely liable to be contaminated. Of those bitten in the face ninety per cent., of those bitten on the hands fifty-three per cent., and of those bitten where the part was protected by clothing twenty-four per cent., were infected. (Anderson.) The excessive frequency of inoculation in bites of the face is largely due to the vascularity of the tissues and to the activity of absorption.

---

[1] Smith's Surgery, vol. i. p. 445.

[2] The Plains of the Great West.

Symptoms.—Inoculation is followed by a period of incubation which varies greatly in length in different cases. The period in the human subject ranges from two weeks to eight months; the most accurate observations seem to fix about forty days as the average period of latency. No constant symptoms are present during this process of incubation. The scar left by the bite sometimes becomes irritable and is the seat of various neuralgic disturbances, while the lymphatic glands in connection with it swell. Small papules beneath the tongue, occurring from the third to the ninth day after the bite, are noted by Anderson.

The onset of the disease is marked by rather vague symptoms. The patient's disposition changes; he becomes gloomy, irritable, and despondent,—and this feature is marked even in young children; the face wears an expression of anxiety and suffering; the heart-action is frequent and irregular; chills succeeded by fever occur at short intervals, and there are generally evidences of disorder of the central nervous system. This period, the "melancholic stage," is of variable duration,—from a few hours to several days,—and is followed by or imperceptibly runs into the active stage, stage of excitement, or "convulsive stage," which is usually ushered in by some stiffness of the neck, twitching of the muscles of the face, pain in the region of the fauces and glottis, and slightly-spasmodic respiration. The tongue is dry, and efforts to quench thirst give rise to violent spasms of the muscles of deglutition and respiration. Mental disorder, marked by delirium, spectral and hysterical illusions, and paroxysms of violent maniacal excitement with active rabid manifestations, are present, but are generally succeeded by lucid intervals. The difficulty of swallowing increases rapidly, and the effort induces fearful spasms of the muscles of deglutition and respiration. Hyperæsthesia increases coincidently with exaggerated reflex excitability, and a current of air, a flash of light, or the jarring of a door is sufficient to excite a violent recurrence of the spasms. The voice becomes weak and husky, "like the bark of a dog;" a profuse viscid salivary secretion, which cannot be swallowed, is expectorated in every direction; præcordial pain, vomiting, excessive thirst, and dysuria add to the general suffering. Albumen and sugar are occasionally present in the urine. The spasms increase in frequency but diminish in force, and the patient either dies asphyxiated in a convulsion, or drifts into the third or "paralytic stage," when, with entire loss of muscular power, he lies utterly prostrate and helpless, but often entirely conscious and rational, despite the exhaustion, until death ends his suffering, an event which usually occurs in from two to five days in adults, while children generally succumb in less than twenty-four hours.

Diagnosis.—There can be little doubt that many nervous disorders, and especially hysterical manifestations, are mistaken for true hydrophobia.

It is also altogether probable that many of the deaths reported from this disorder have been due to other and less serious maladies, and that the influence of terror, acting upon weak and diseased nervous systems, has many times served to intensify conditions which were otherwise not necessarily fatal. That true human rabies is an exceedingly rare disease cannot be denied. It is evident, therefore, that a correct diagnosis is a matter of extreme importance.

The diseases from which human rabies must be distinguished are tetanus and hysterical convulsions. The absence of a recent wound, the long period of incubation, the fact that spasms are *clonic* and involve the muscles of deglutition and respiration, and not those of mastication, the absence of general muscular rigidity or spasm, and the presence of spectral illusions and maniacal delirium, should very clearly distinguish rabies from tetanus. From hysteria the disease may usually be distinguished by the age and sex of the patient, the suddenness of the onset, the violence of unimportant symptoms, and the absence of symptoms which most certainly imperil life.

Pathology.—The nature of the virus which induces rabies has not yet been ascertained; but it seems probable that it is of bacterial origin, and that the specific germs, after being introduced into the tissues of a healthy animal, remain dormant during a period of incubation, and then manifest their presence by inflammatory changes at the seat of inoculation, together with the formation of some specific and deadly but unisolated ptomaine, which entering the blood exerts a poisonous and destructive influence upon the central nervous system.

Morbid Anatomy.—The post-mortem appearances point to the action of some blood-poison,—viz., fluidity of the blood; ecchymotic spots beneath the pleura, pericardium, and membranes of the brain and spinal cord, with minute hemorrhagic infarctions of the smaller vessels and miliary abscesses in the gray matter; organic changes in the ganglion-cells of the ninth, tenth, and eleventh cranial nerves; and copious infiltration of leucocytes into the perivascular spaces of the cerebral cortex and the medulla oblongata. Cheadle has discovered rod-like bodies resembing bacteria in the extravasations of blood in the same region. Klebs has found highly-refractive granular corpuscles arranged in bands or stellate groups in the lymphatic and submaxillary glands; and Gibier has recently claimed the discovery of a micro-organism constantly present in pigeons inoculated with the virus of rabies. Thus far, however, the discovery of a specific microbe in rabies has not been confirmed.

Treatment.—The fact that there is no remedy or method of treatment which either modifies the progress of the disease or limits its fatal effects renders the importance of a perfect prophylaxis self-evident.

Prophylactic measures are directed, first, to the destruction of the virus immediately after its introduction into the tissues and while it is yet localized in the wound, and, secondly, to efforts to neutralize the virulence of the poison before it can enter the system, or rather to render the bitten person unsusceptible to its effects by inoculating him with an attenuated rabic virus during the last stages of its incubation, after the method of Pasteur.

The first object is best attained by promptly encircling the limb at a point some distance above the bite with a tightly-drawn ligature, to arrest the circulation and prevent absorption. The wound should next be vigorously sucked with the lips, if there are no abrasions upon them, or by a cupping-glass, and as soon as possible should be bathed or immersed in a hot solution of corrosive sublimate, one to one hundred, for half an hour, and then cauterized freely with a red-hot iron, fuming nitric acid, or pure undiluted carbolic acid: nitrate of silver is too shallow a caustic to be of any value. The ligature must be removed as soon as the cauterization is completed. As the pain of the cauterization is intense, an anæsthetic will usually be required; after this the part must be enveloped in an antiseptic dressing and kept at rest until healing is completed. When done with a free hand, this treatment is more reliable than excision of the part, though excision should be resorted to if the wound has already healed.

Dogs are very filthy animals at best, feeding constantly upon all sorts of putrid matter, and their teeth are liable to be charged with poisons but little less deadly than that of rabies; their bites cause not only punctured and lacerated but also poisoned wounds, and for these reasons all bites inflicted by a dog, whether the animal be suspected of rabies or not, should be subjected to thorough cleansing and cauterization. The bitten person should avoid the use of all intoxicants.

The second form of prophylaxis, by inoculation with attenuated rabic virus, has been extensively practised in France and Russia under the direction of Pasteur and his pupils, with results which are claimed to be highly satisfactory. Grancher asserts that the mortality in persons bitten by mad dogs was reduced in Paris in 1888 to seventy-seven hundredths of one per cent. by inoculation, against fifteen and nine-tenths per cent. in bitten persons who were not submitted to this treatment.[1] The attenuated virus is obtained from the dried spinal cords of rabbits dead of rabies artificially produced by inoculation from dogs known to be rabid, and is introduced in the form of emulsion in water by means of a Pravaz syringe.

The efficacy of this treatment is denied by very competent authority, and it is asserted that death has resulted from its employment. The question of its value may therefore be regarded as still unsettled, although the weight of evidence seems to be in its favor. Certainly cauterization of the wound should not be neglected even if the protective inoculations are employed. It would also seem rational to use some method of internal medication during the incubative stage, similar to that employed in syphilis, in the hope of either eliminating the poison or rendering it inert in the tissues.

---

[1] Medical News, December, 1888.

The symptomatic or curative treatment is very unsatisfactory. The most that can be done is to relieve the sufferings of the patient. As the disease is rapidly fatal, there is little time for the employment of remedies. Owing to the difficulty or impossibility of swallowing, all nourishment should be administered by the rectum, and hypodermic injection is the only practicable method of medication. The remedies which possess any value are few. Chloroform, chloral, morphine, atropine, curare, and pilocarpine are probably the most reliable. Three recoveries are claimed (by Offenburg, Polli, and Watson) to have followed the use of curare. The dose in one case was two-thirds of a grain and was repeated at intervals as the effects passed off. In the second case three and a half grains were given in five and a half hours to a child of twelve years, and in the third it was given in doses gradually increased from one-sixteenth to one-half grain every three hours. The drug arrests the rabic spasms by paralyzing the motor nerves, and therefore requires caution in its use. The patient should be kept in a dark, quiet, well-ventilated room, and be protected from draughts of cold air, noise, and all sources of excitement. Nourishing broths, stimulants, and liquids must be given by enemata to sustain the patient's strength.

Glanders.—Glanders is a disease occasionally prevalent among horses, and is sometimes communicated to man by inoculation or by absorption of the virus through the mucous membranes. It is due to a specific micro-organism, the bacillus mallei, first isolated and cultivated by Schütz and Loeffler in 1882, though previously seen by Christatt and Keiner and by Bouchard, Capitan, and Charrin. It is a small, rod-like bacillus, resembling the bacillus of tubercle. It may be cultivated in solid blood-serum, potato, beef peptone, and agar-agar jelly : the cultures retain their vitality for a year.

In horses the disease first appears upon the nasal mucous membrane, in the form of nodules or of small, deep, excavated ulcers, surrounded by marked cellular infiltration. The submaxillary glands become involved early, and the disease spreads by metastasis to other organs.

In man the inoculation with the virus of glanders is followed in about eight days by chills and general febrile excitement, and by the appearance of nodules in the mucous membrane of the nostrils; deep, foul ulcers soon after appear from rupture of the nodules, and the nostrils discharge a thin, offensive, sanious pus. The submaxillary and cervical glands become involved, the face is swollen, the nodules break down into deep, excavated ulcers which appear upon the skin, the mucous membranes of the air-passages and of the digestive tract are similarly attacked, and vomiting and diarrhœa are present. The febrile condition assumes an adynamic form, with low muttering delirum, extreme prostration, and evidences of general septic infection.

The diagnosis is difficult, and in the very early stages almost impossible without some antecedent history. The disease has been mistaken for rheumatism, for varicella, and for small-pox, and in its later stages for pyæmia and typhus fever.

The treatment should be supporting and mildly stimulating. If a point of infection can be discovered, it should at once be destroyed with fuming nitric acid. Internally quinine in large doses, three to five grains every six hours to a child of five years, with the mineral acids or the tincture of the chloride of iron, should be administered. The diet should be nutritious, and moderate stimulation by wine, whiskey, or porter will be valuable. Locally the nostrils and throat should be frequently washed or irrigated with some active detergent lotion, as Condy's fluid or Thiersch's solution, and afterwards well dusted with iodoform by means of an insufflator. Ulceration upon the skin should be similarly treated, and, if deep and foul, should be actively stimulated by dilute nitric or hydrochloric acid.

The treatment is very unsatisfactory, and few cases recover.

WOUNDS POISONED BY CONTACT WITH THE FLUIDS FROM RECENT DEAD BODIES.

Wounds of this character are infected either with a specific germ, or with the products of putrefaction resulting from the action of germs upon dead animal matter. They are very seldom encountered in childhood, unless accidentally received through the contact of an abrasion or wound in playing with or handling the bodies of dead animals. When met with, the peril equals that of similar wounds in the adult, and for this reason they merit brief consideration. In the adult they are of much more frequent occurrence, and occur in the form of dissection-wounds, or the wounds received by butchers, "fallmasters," and persons engaged in handling half-putrid hides.

It has long been known that dangerous and even fatal consequences follow wounds received in the dissection of human bodies. Two forms of poisoning, apparently depending upon the virulence and activity of the poison, are met with,—the mild and the severe. A third form, perhaps not properly a wound, is occasionally seen in the form of dark-colored warty excrescences, the so-called "anatomical tubercle," or verrucæ necrogenicæ, on the hands and about the knuckles of persons engaged in handling dead bodies. As this third form is due to the influence of an irritant, removal of the cause and the application of mild antiseptic lotions—as weak sublimate solution or a borated ointment—are all that will be required in the way of treatment.

The mild form of poisoned wounds is attended by a moderate degree of inflammation, with some redness and tenderness along the course of the lymphatics leading from it, and more or less constitutional disturbance. This usually subsides in a few days, or culminates in the formation of a circumscribed abscess at the seat of the wound or in the axillary glands. The febrile excitement disappears with the discharge of the pus. The prognosis is favorable, and little is required in the way of treatment, except to modify the severity of the local inflammation by cooling lotions and the evacuation of the pus as soon as it can be detected. If the patient is feeble, quinine with the mineral acids will hasten recovery.

The severe or acute form of dissection-wounds, usually received in the dissection of a recently-dead human body, or by contact of a wound with animal matter which has not advanced too far in decomposition, is followed by the rapid development of symptoms of the most alarming character, indicating the local effects and constitutional consequences of a virulent specific poison. Undoubtedly the condition of health of the wounded person, as well as the character or source of the poison with which he is infected, modifies the final result. Persons in feeble health or exhausted by overwork are ill prepared to resist the effects of the toxic agent, and the wounds contaminated during the dissection of bodies in which death has resulted from puerperal peritonitis, scarlet fever, or erysipelas are peculiarly liable to be followed by fatal results.

Usually at the end of twenty-four or forty-eight hours after contamination the wound becomes painful, and a minute vesicle or pustule appears at the seat of lesion. This is rapidly followed by an extension of the inflammation towards the body; a red and painful line marks the course of the lymph-vessel leading to the axilla, the epitrochlear and axillary glands become indurated and tender, and the hand and arm swell rapidly and enormously. Severe and frequently-recurring chills followed by febrile heat, violent pain in the back, deadly nausea with constant efforts to vomit, rapid and feeble pulse, extreme restlessness, intermittent delirium, and utter prostration mark the constitutional effects. In the worst cases gangrene attacks the wound and extends to the hand and arm, abscesses form on the axilla and beneath the pectoral muscles, deep and violent erysipelatous inflammation extends over the side of the chest from the clavicle to the buttocks, and the skin, greatly congested and indurated, becomes dusky brown or black in color from the supervention of gangrene. The constitutional symptoms are rapidly aggravated, and low muttering delirium, frequent, feeble, or imperceptible pulse, cold damp skin, and extreme depression of all the vital powers mark the approach of death, which usually occurs from coma and exhaustion. The fatal result sometimes occurs very early; in one case of which I have personal knowledge, death took place forty-eight hours after the onset of the symptoms.

The poison usually finds entrance through some trifling wound on the finger or hand, as the puncture of a needle or spicula of bone; but any scratch or abrasion may absorb it. Sir James Paget believes that the poison from which he suffered was absorbed by the unbroken skin from the pleuritic fluid with which his hands were bathed during a post-mortem. "It soaked through the skin. I had no wound or crack of any kind."[1]

---

[1] Clinical Lectures.

Hayward states[1] that he wounded his forefinger very slightly with several needles, and soon afterwards touched the intestine of a child that had recently died of peritonitis. Fourteen hours afterwards he was aroused from sleep by intense pain in the wounded finger, which soon became swollen, livid, and finally gangrenous. Severe constitutional symptoms followed, but he recovered in a month.

In my own case the poison was absorbed through an abrasion on my left middle finger, from the fluids in the peritoneal cavity of a man who had died eight hours previously from gangrene of the bowels. Forty hours afterwards the hand became excessively painful, and constitutional symptoms of very great severity followed rapidly. Despite free incision, the hand and arm swelled to double their natural size, and abscesses formed in the course of the lymph-vessels. The symptoms subsided in a fortnight, but the hand remained swollen, stiff, and useless for many months.

All cases do not terminate so happily. Travers[2] mentions the case of a student who, after puncturing his finger while examining the body of a man that had died in the hospital, himself expired within forty hours afterwards from the effects of the puncture, with symptoms nearly resembling those of hydrophobia. Dr. Christy, in this city, punctured his finger with a needle while finishing an autopsy upon a man dead of erysipelas; at the end of the second day afterwards his arm showed marked evidences of poisoning, and forty-eight hours later he died from its effects. The literature of surgery abounds with similar histories.

The nature of the specific poison (or poisons) has not yet been absolutely determined, but it undoubtedly belongs to the ptomaines or volatile alkaloidal products of putrefaction of animal matter. Bergmann in 1866 first isolated a crystallizable substance, sepsin, from putrid blood, which when injected into the tissues of animals he found to be actively poisonous by the production of a fatal form of septicæmia. The investigations of Zuelzer and Sonnenschein, Selmi, Rörsch and Fasbender, Brieger, Gautier, and others led to the discovery of a number of other volatile alkaloids or ptomaine substances (Selmi) in dead human or animal bodies and in decomposing albuminous matter, among which may be mentioned putrescine, mydaleine, choline, mydatoxine, tetanine, etc. Several of these putrid products are isomeric with the vegetable alkaloids and correspond more or less closely with them in their physiological effects, all of them being actively poisonous and rapidly destructive to life when injected into the tissues of the lower animals.

Treatment.—The treatment of poisoned wounds of the character under consideration necessarily varies with the period at which it is instituted and the severity of the symptoms. All wounds received in post-mortem examinations, or in any way liable to become infected by the poisonous emanations from dead animal matter, require prompt and energetic treatment. The wound should always be well washed with soap and running water, and immediately afterwards cauterized with fuming nitric acid, strong hydrochloric acid, or acid pernitrate of mercury. Nitrate of silver is entirely too feeble an agent to be of any service; it forms an insoluble albuminate of silver, which covers the wound like a scab and interferes with the escape of serum; its effects are very irritating to the wound, but it does not destroy any poison which may have entered it. Where no wound exists, but the hands have been brought in contact with putrefying animal matter, they should always be thoroughly cleansed with soap-and-water and afterwards washed with strong acetic acid.

---

[1] Remarks on Dissection-Wounds, American Journal of the Medical Sciences, January, 1844.

[2] Essay on Constitutional Irritation.

When the poison has been absorbed and local and constitutional symptoms appear, the treatment must be supporting and eliminative. Morphine or opium will be required to relieve pain, lessen the shock of the onset of the attack, and secure rest. In my own case a full dose of morphine given hypodermically afforded marked relief, and probably enabled me to resist the depressing influences of the poison.

Mild catharsis by calomel or Rochelle salt will be useful by increasing hepatic activity. Quinine in large doses—six to eight grains every four hours to an adult—will, next to morphine, prove the most valuable remedy, and champagne or brandy-and-soda will be useful in allaying gastric irritability and supporting the strength. The diet must be of the most nutritious quality,—concentrated animal broths, beef peptonoids, milk, eggs, etc.,—and a moderate quantity of wine will be required. No actively-depleting measures should ever be adopted, and, if signs of depression are urgent, active stimulation by wine, brandy, ether, etc., is demanded.

The condition of the wounded part will require attention, but no further cauterization of the wound is permissible. The limb should be enveloped in cloths wrung out of a hot antiseptic solution, and slightly elevated. If the swelling increases rapidly, free incisions must be made in the part, so as to afford sufficient outlet for the putrid serum or pus which may be present and to relieve the tension of the skin. This is especially necessary when the inflammation assumes the form of diffused cellulitis or when gangrene attacks the skin; and the incisions must be free enough to liberate the pus and permit the discharge of dead cellular elements. Abscesses usually form at the bend of the elbow, in the axilla, or under the pectoral and trapezius muscles. They must be evacuated by free incisions as soon as detected, and drainage secured afterwards. In cases of deep-seated local tenderness and induration without distinct fluctuation, it is always wise to search for pus by introducing the needle of a hypodermic syringe or aspirator, and if a deeply-located abscess is reached it must be opened at once and treated antiseptically. Recovery is always tedious, and the health is often permanently impaired.

COMPLICATIONS OF WOUNDS.

It is probable that every variety of wound-complication depends upon septic contamination and is therefore preventable in a majority of cases. These complications are met with under two conditions: first, morbid processes depending upon specific forms of microbic infection,—tetanus, erysipelas, spreading gangrene, and phagedæna, and in a mild form lymphangitis and lymphadenitis; second, constitutional disturbances depending on septic germs present in suppuration,—sapræmia, septicæmia, and pyæmia.

MORBID PROCESSES DEPENDING UPON SPECIFIC FORMS OF MICROBIC INFECTION.

TETANUS.—This terrible complication is met with at all periods of life, at all seasons of the year, and after every imaginable form of wound. Age does not influence its occurrence, and it is encountered in about equal frequency in children and in adults, nearly sixty per cent. of the cases occurring between the tenth and the thirtieth year. It is a disease marked by violent continued *tonic* spasms, involving all the muscles of the body (except those of the hands), and most severely affecting the muscles of the back and those of mastication, deglutition, and respiration. The spasm is continuous and unremitting, and is aggravated at variable intervals by the occurrence of sudden paroxysms during which the intensity of the muscular contraction is violently increased. It may follow the most trifling injury. I have seen it follow a slight wound of the thumb in a boy of seventeen years, a crush of the tip of the ring finger in a child of seven, a lacerated wound of the skin over the knee in a boy of nine, and an operation performed by a dentist upon an inflamed tooth in a boy of thirteen. No wound is free from this danger. Exposure to cold after a wound is a common predisposing cause. On the other hand, prolonged heat during the day, followed by damp, chilly nights, seems to favor its development.

It is probable also that wounded persons who sleep near the earth are more liable to be attacked than those who occupy upper rooms.

No characteristic train of symptoms can ever be relied upon as indicating the approach of tetanus, but the first complaint which attracts attention usually indicates the nature of the malady. The attack comes on generally from the second to the tenth day after the injury. Mr. Poland[1] tabulates two hundred and seventy-seven cases, as follows:

"Previous to the tenth day	130 cases, of whom 101 died.
From the tenth to the twenty-second day	126 cases, of whom 65 died.
Above twenty-two days	21 cases, of whom 8 died."

My own observations in thirty-two cases confirm the opinion that an early attack is always extremely violent and rapidly fatal. In all the fatal cases which I have seen, the attack came on before the tenth day, in some of them as early as the third day, and in most before the sixth day after the injury. The cases which occurred after the tenth day were usually milder and more easily controlled, though they did not all recover.

---

[1] Holmes, System of Surgery, 3d ed., vol. i. p. 202.

Usually the first symptoms of which the patient complains are slight sore throat, with some stiffness and soreness about the back of the neck; and this complaint is usually made at the morning visit. If the face of the patient is now closely scrutinized, a peculiar expression of countenance will be observed; the brow is very slightly wrinkled, the eyelids and lips seem drawn at the angles, and if an attempt is made to protrude the tongue it is done with difficulty, and the jaws cannot be separated widely.

The wound almost always assumes a dry, unhealthy appearance, and repair ceases. The disease has already commenced. The muscles of the neck, back, chest, and abdomen rapidly become involved in the general rigidity, the tightly-drawn lips compress the teeth, the eyelids hug the eyeballs and give the eyes a staring expression, the brow is corrugated, and the face grins with the *risus sardonicus.* The pain of a universal cramp seizes the muscles, the body is bent backward, the jaws become clinched, deglutition and respiration become difficult, and violent paroxysms of spasm increase the suffering and imperil life by impeding respiration. During these paroxysms the jaws, if separated, close with a snap, and the tongue when caught between the teeth is terribly bitten; respiration is almost impossible, the face is livid, and the breath is forced through the clinched teeth with a hissing sound, and, carrying the saliva with it, covers the lips with a bloody foam. The tongue is foul, and the skin bathed in perspiration. The pulse is not greatly accelerated except during the paroxysms, and the temperature seldom exceeds 103° F. except just before death, when it has been known to reach 112° F. The mind remains clear until the end, unless disturbed by the influence of drugs given to relieve the spasm. Death occurs by asphyxia or exhaustion.

The exact pathology of the disease is obscure, and the pathological appearances are by no means constant or characteristic. Lockhart-Clarke, Clifford-Allbutt, Dickinson, and others have described changes in the medulla and spinal cord, transparent exudation around the vessels, greater in the gray than in the white structures, granular degeneration, or actual cavities, in the gray substance, exudations in the gray matter of the posterior columns, and alterations in the ganglion-cells. Other observers, equally careful and competent, have failed to discover these changes. It is evident that the disease is not a myelitis and that it is not inflammatory.

The recent observations of Nicolaïer and Rosenbach seem to establish the fact that the disease is septic in origin and depends upon the entrance of a specific microbe or bacillus into the wound. Verneuil contends that the specific virus exists in the excretions and emanations from horses, and that wounds so contaminated are very liable to be followed by tetanus.[1]

---

[1] Revue de Chirurgie, October and December, 1887.

Nicolaïer has succeeded in producing a disease similar to tetanus by introducing garden earth beneath the skin of guinea-pigs and rabbits; and Beumer and Rosenbach have obtained similar results by inoculating mice, rabbits, and guinea-pigs with pus taken from the wounds of tetanic patients, and also from cultivations (in blood-serum) of the bacillus obtained from the same source. Hochsinger has produced tetanus in rabbits by injecting the blood drawn from a tetanic patient during life. Brieger[1] isolated four toxic ptomaines from cultivation of the bacillus tetani,—namely, tetanine, tetano-toxin, toxin-muriate, and spasmo-toxin,—all of which produce convulsive movements with well-marked tetanic symptoms in animals (rabbits); and he has also isolated tetanine from the amputated arm of a man suffering from tetanus. These observations seem to establish beyond cavil the dependence of the tetanic condition upon certain specific toxic agents produced by the action of a bacillus upon the albuminous matter in the wound; these toxic agents influence the medulla oblongata and spinal cord in a manner similar to strychnine; and they also prove that the disease is communicable from one animal to another and probably to man, though transmission from man to man has not been proved.

The diagnosis of tetanus in childhood is not difficult: the previous existence of a wound, the manner of onset of the disease, the more or less rapid progress and constantly-increasing severity of the tonic contractions, the inability to open the jaws or protrude the tongue, and the absence of delirium or spectral illusions are unfailing guides to a correct diagnosis.

The prognosis is generally unfavorable. The venerable Prof. S. D. Gross stated that in a practice of fifty years he had seen but three recoveries. Hennen never saw a recovery from acute traumatic tetanus. During our late civil war three hundred and sixty-three cases were reported, with twenty-seven recoveries. In my own personal experience seven cases have recovered in thirty-two cases attacked, and I have reliable information that two other cases recovered in the practice of another surgeon in this city. Death may occur from the second to the twentieth day or even later; in one case in my own practice it occurred on the sixteenth day.

Treatment.—The treatment is both local or prophylactic, and general or symptomatic. The local treatment consists in the removal of every possible source of irritation or infection from the wound, and the protection of the wound-surfaces from contact with the germ-charged air or with other and more tangible sources of contamination. A rigid antisepsis after thorough cleansing of the wound is the best prophylactic measure. Care must be taken that no impure water, or water obtained from troughs used by horses, and possibly contaminated by their excrement, should ever come in contact with the wound.

The patient must be kept in a warm, quiet room, preferably on an upper floor, and must be carefully guarded from draughts of cold air. If the wound is sloughing and unhealthy, it must be cleansed as thoroughly as possible and enveloped in a warm antiseptic dressing. The medicinal treatment is very unsatisfactory, and in the majority of cases is confined to efforts to prolong life and to afford some degree of relief from the terrible suffering. The disease is fearfully exhausting, and the strength must be supported by a nutritious liquid diet,—rich, strong broths, milk, eggs, etc.,—with a moderate quantity of wine or brandy. As it is often impossible for the patient to swallow anything, his food must either be given by rectal enemata, or preferably by means of the stomach-tube, introduced through the nostril and pushed well down the œsophagus. A few ounces of broth or other liquid aliment can easily be thrown into the stomach through this tube by means of a syringe, and can be repeated at intervals of one or two hours without annoying the patient or adding to his distress.

---

[1] Virchow's Archiv, Bd. xcii., H. 3.

The remedies which possess any real value in mitigating the violence of the disease are few in number. Chloral, bromide of ammonium, pilocarpine, Calabar bean and its alkaloid eserine, coniine, atropine, and morphine are the most valuable.

Chloral, alone or in combination with the bromide of ammonium, is probably the remedy upon which most reliance can be placed, and in my own experience has yielded the best results. It must be given in doses sufficiently large to control the muscular spasms and to procure sleep; after this is attained the patient must be kept in a condition of mild chloral intoxication until the violence of the attack has passed. It must be given in full doses, but its effects should be watched, and as soon as the spasm relaxes it should be withdrawn temporarily or the dose lessened and the bromide of ammonium substituted for it. Five grains of chloral with an equal quantity of the bromide may be given hourly or every second hour to a child of five years, as long as the intensity of the spasms continues, but it must be withdrawn as soon as relief is obtained. Owing to its tendency to weaken the heart, this effect must be counteracted by moderate alcoholic stimulation and an abundant nourishing diet. In four out of seven cases of recovery in my own experience, favorable results followed the combination of chloral with bromide of ammonium.

Pilocarpine given hypodermically has recently been employed with success by Dr. L. Cassati, of Forlì,[1] in three cases (in one after failure of chloral and bromide of potassium). The dose given was one centigramme every two hours night and day, and in one very severe case seventy centigrammes were given in fifteen days. Beneficial results have been obtained from eserine given in a daily quantity equal to one-fourth or one-third of a grain; the tincture of Calabar bean is not reliable, or at least has yielded no results in my hands.

The bromide of coniine has been successfully used by Demmer, in a single dose of one-sixth of a grain to a boy, hypodermically, followed by one-twelfth-grain doses internally every two hours. Atropine and morphine are useful by temporarily allaying the violence of the spasm and in securing rest: in one instance recovery followed the combination of morphine with bromide of potassium.

---

[1] Raccoglitore Medico.

Where recovery occurs, there is a gradual relaxation of the tonic spasm, the paroxysms become milder and less frequent, and the patient is convalescent in from two to six weeks; some rigidity of the jaws remains for many weeks after the disease has terminated.

LYMPHANGITIS.—Inflammation of the lymphatic vessels occurs as an occasional consequence of every variety of injury, whether wound, abrasion, or sprain, and is more frequently met with in childhood than in adult life. An irritative or inflammatory process starts in the wound and involves the lymph-radicles in the vicinity, spreading from thence to the larger lymph-channels; these become inflamed, and extend in red painful lines towards the trunk, involving the glands with which they communicate. Commonly the attack is ushered in by a chill followed by febrile excitement, with nausea, headache, thirst, and prostration of strength. If several lymphatics are involved, the part becomes hot, painful, and œdematous, and the glands in the line of the inflamed channels are swollen and tender.

The inflammatory process involves the entire structure of the walls of the lymph-vessels, and may spread from thence to the adjacent tissues; the contents of the vessels become turbid or even puriform, and the vessels themselves may be obstructed by coagula or obliterated by inflammatory thickening. In severe cases the process ends in suppuration in the lymph-vessels and in the surrounding connective tissue, with sloughing of the adjacent parts. In mild cases resolution occurs in a few days; the red lines disappear from the skin, and the tissues regain their natural appearance. Some œdema is apt to remain for some time after the subsidence of the inflammation, and the swollen glands continue to be tender and painful. This swelling usually subsides slowly and ultimately disappears, but in severe cases or in badly-nourished children may end in suppuration, which does not cease until the entire gland is destroyed.

The occurrence of lymphangitis indicates the existence of a mild form of sepsis; but, unless dependent upon infection of the wound with some of the products of decomposition, it is almost free from danger.

Treatment.—The wound, if one exists, should be thoroughly cleansed and treated by warm antiseptic fomentations; if collections of pus exist, they must be freely opened by incisions, so as to allow escape for the discharges. If the limb is hot and tender, cool anodyne lotions, as the common lead-and-laudanum lotion, will be serviceable; and elevation of the limb will add to the comfort of the patient. Internally a mild saline cathartic followed by full doses of quinine should be given, and will usually be all the medication required.

LYMPHADENITIS.—The lymphatic glands are inflamed as a secondary result of the absorption of morbid or septic material from a wound, or by extension from an inflamed lymphatic vessel. It may also result from direct injury to the gland. The gland swells, and becomes hot, tender, and firmly attached to the surrounding structures. The blood-vessels dilate, an exudation of leucocytes invades the gland, blocks the lymph-channels, and extends to the surrounding tissues, and the gland is hard, resisting, and painful. The ultimate result depends upon the severity of the process and upon the mode of treatment adopted. In mild cases the inflammatory process abates, the hyperæmia diminishes, and resolution follows. The exuded leucocytes are absorbed or undergo fatty degeneration, and the gland softens and decreases in size. In severe cases the tension within the capsule of the gland increases until the capillaries are obstructed by the pressure, and necrosis of its structures follows. An abscess speedily forms, and when opened discharges a quantity of grumous pus and broken-down gland-tissue. Sometimes the inflammation assumes a chronic form, and the gland ceases to be painful, but remains swollen and indurated for an indefinite period. Having once been inflamed, a gland rarely returns to a perfectly normal condition, but remains as a possible focus for future tubercular manifestations.

Treatment.—Cleansing of the wound and removal of all sources of irritation, with rest to the part, are indispensable elements of treatment. During the early acute stage cold by means of an ice-bag affords relief by lessening the hyperæmia and thus retarding suppuration. Later, warm fomentations are usually more agreeable to the patient, and when it is evident that suppuration cannot be prevented they should always be employed to hasten that result. As soon as pus can be detected it should be evacuated by an incision large enough to allow free escape for the pus and débris of the disintegrated gland-structure. The cavity should be washed out with a warm solution of boric or carbolic acid, and hot antiseptic fomentations continued until the discharge ceases. When the pus shows a disposition to burrow beneath the skin, the edges of the wound and the track of the forming sinuses must be laid open, the pyogenic membrane which covers the surface destroyed, and the cavity packed with carbolic or iodoform gauze, so as to secure healing from the bottom of the cavity. When the glands do not suppurate, but remain swollen and tender, resolution may be hastened by the application of an ointment of the iodide of lead or iodide of cadmium. The general health of the patient requires attention, and tonics and nutritious food are indispensable.

Erysipelas.—An "acute, spreading, and infectious inflammation of the skin, or of the subcutaneous connective tissue," is occasionally met with as a complication of wounds which have not been well cared for or which occur in feeble cachectic persons with bad sanitary surroundings. Its origin is undoubtedly microbic, and due to infection (of the wound) with a specific materies morbi, the *streptococcus erysipelatosus*, which enters the tissues through a lesion on the surface, no matter how insignificant, and diffuses itself by the lymph-channels through wide but sharply-defined areas or zones of tissue, and gives rise to distinct, severe, and often destructive forms of inflammation in the invaded structures. What seems to be positive evidence of the dependence of erysipelas upon microbic infection has been furnished by the observations of Orth, Lukomsky, Tillmanns, and Koch, confirmed by the successful cultivations of the specific microbe by Fehleisen, and the transmission of the disease to animals and to man through inoculation from these cultivations. Erysipelas is very rarely encountered in childhood, and is usually very mild in its course; but in very young infants it is extremely fatal. Most of those attacked within the first month after birth perish. It is not uncommon in infancy, and generally starts from an abrasion on the lips, at the angle of the mouth, or upon the genitals. It almost invariably assumes the mild or cutaneous form, and, although attended by an active febrile disturbance, is nearly always easily controlled. As a complication of wounds it may be entirely prevented by a careful antisepsis. A mild mercurial cathartic, followed by tonics, as quinine and tincture of the chloride of iron, with local applications of weak solutions of sublimate or the ordinary lead lotion, is commonly all that is required. For further details the reader is referred to the article on erysipelas.

Gangrene and Phagedæna, except as seen in the specific form of noma or cancrum oris, or when dependent upon complete obliteration of the blood- and nerve-supply of a part, are extremely rare in childhood, and spreading traumatic gangrene is almost unknown. I have never met with it before the twentieth year.

CONSTITUTIONAL DISTURBANCES DEPENDING ON THE SEPTIC GERMS PRESENT IN SUPPURATION.

Three forms of blood-contamination, closely related to one another and frequently occurring together in the same subject, though dependent upon distinct conditions, are met with as results of wounds at all ages,—viz., *sapræmia*, *septicæmia*, and *pyæmia*. Although less frequent and far less serious in childhood than in adult life, they nevertheless merit brief consideration, as the most serious and fatal of all complications.

A certain degree of pyrexia follows nearly every severe form of wound or injury, even when subcutaneous and aseptic,—due in part to the local irritant effect of the traumatism, but probably in greater degree to absorption of some leucomaine-substance which is developed in the fluids poured out at the seat of injury, and which possesses qualities capable of temporarily disturbing the functions of the heat-centres: a mild form of so-called traumatic or "inflammatory" fever results. This soon disappears, probably by elimination of the exciting cause.

Sapræmia, Putrid Intoxication, or Toxic Mycosis of the Blood.—When unsterilized air gains access to a wound, certain micro-organisms are carried with it, and, if among them are those saprophytic germs which thrive in the various putrescible fluids that bathe its surface, "they break up the complex organic compounds and reduce them to simpler forms." (Cheyne.) Decomposition, fermentation, and chemical changes result, and the various unstable alkaloidal products of putrefaction are formed abundantly. As already stated elsewhere, many of these animal alkaloids, or ptomaines, possess intensely noxious properties, and are actively poisonous to all animals and to man. They are not destructible by boiling, even if it be prolonged for ten hours. They require no period of incubation, but, when absorbed into the blood in sufficient quantity, immediately develop most violent and dangerous symptoms, and may destroy life in a few hours. The materies morbi is a chemical product resulting from putrefaction of the albuminous wound-secretions; it is not a germ, but is the product of germ life, and the chain of symptoms to which the term *sapræmia*, *septic intoxication*, or *putrid intoxication* is applicable results from its toxic effects upon the blood and the nerve-centres. Every imperfectly-drained wound, abscess, or granulating surface which becomes infected is a source of danger from absorption of these putrid substances. No germs are present in the blood immediately after death. The blood coagulates imperfectly, the red corpuscles are disintegrated, the lining membrane of the vessels and that of the heart are darkly stained, and decomposition progresses rapidly. The symptoms of putrid intoxication are those present in the bad forms of dissection-wounds,—viz., severe chill, followed by sudden rise of temperature to 104° or 106° F., vomiting, thirst, frequent or irregular pulse, delirium, and extreme prostration; and if the quantity of the poison absorbed is large, or if absorption continues, collapse, bloody diarrhœa, coma, and death follow one another with startling rapidity.

The treatment involves efforts to prevent further absorption of putrid material, by cleansing and draining the wound. This must be done by washing its surface with antiseptic and detergent lotions, relieving tension by the removal of sutures or by evacuating abscesses, affording abundant outlet for the discharges, and guarding against further infection by antiseptic dressings. The internal treatment should be eliminating and supporting,—free mercurial catharsis if prostration is not present, followed by full and frequently-repeated doses of quinine, with nourishing food and moderate alcoholic stimulation.

SEPTICÆMIA.—This condition is caused by infection of the living tissues, and later of the blood, with certain specific micro-organisms, which, after a brief period of incubation, multiply rapidly in the blood and tissues, causing capillary embolisms and thromboses, impairing the nutrition, "deranging the function of important organs" (Senn), and causing the formation of ptomaines within the living body. The effects do not depend upon the dose: the smallest quantity inoculated into the tissues is followed by the specific results in all their intensity. The blood after death teems with microbes (most commonly the staphylococcus pyogenes albus), and if inoculated into another animal produces the same specific train of symptoms as were observed in the first subject. When once established, the tendency of septicæmia is towards death: there is a gradual and progressive increase of all the symptoms, without any improvement, such as is seen occasionally in sapræmia after the source of the poison in the wound is removed.

Two forms of septicæmia, the acute and the chronic, are recognized. The acute form is probably complicated by the coexistence of the sapræmic condition. The symptoms therefore vary with the nature of the attack. Ordinarily in the acute form they are those of sapræmia. The wound shows some evidence of inflammation,—is hot, painful, and contains a small amount of pus. The attack is usually preceded by a distinct rigor, followed by rapid increase in temperature; there are nausea, thirst, headache, watchful, anxious delirium, feeble, frequent pulse, rapidly-alternating temperature, and marked loss of strength. The urine is scanty and albuminous, and the bowels are greatly relaxed. Collapse followed by coma precedes death, which occurs from the fourth to the seventh day. In the chronic form the symptoms are milder, and the disease runs a more protracted though rarely less fatal course, sometimes lasting for three weeks, the skin in the mean time being covered by petechial spots, or by an eruption resembling that of scarlet fever. Pneumonia, bronchitis, or pericarditis may hasten the fatal result.

The morbid changes are similar to those seen after sapræmia: the serous cavities contain bloody serum; the liver, spleen, and lungs are congested and softened; the blood is almost diffluent and contains micro-organisms (staphylococcus pyogenes albus) in abundance, but abscesses are extremely rare.

Treatment.—The wound should be drained and disinfected as advised in sapræmia, in the hope of preventing further infection. Beyond this the general treatment consists in supporting the strength by nutritious food, moderate stimulation, and full doses of quinine. Sulphurous acid, hyposulphite of sodium, and salicylic acid are worthy of trial; but the treatment is generally very unsatisfactory.

Pyæmia.—This term is applied to a pathological condition which, though intimately related to sapræmia and septicæmia, differs from both of them in the clinical fact that during its progress secondary or metastatic abscesses form in various portions of the body, and that fever of an intermittent character is commonly present. Occurring only while the suppurative and putrefactive processes exist in some part of the body, it evidently depends upon contamination of the blood by some materies morbi present in the suppurating part, most probably by the micro-organisms of suppuration, and possibly with other forms of microbic infection. The noxious element probably gains access to the blood through the medium of a suppurating surface, by first infecting the minute clots or thromboses which are so abundant in the capillaries at the surface of a wound, and which under the influence of the microbes of suppuration do not organize, but break down in minute semi-purulent fragments, and, in the form of infected emboli, are disseminated to every part of the body by the blood-stream. They are finally arrested in the smallest vessels or capillaries, where they cause hemorrhagic infarctions or localized necroses and become the foci for new septic inflammatory processes, ending in the formation of abscesses. Every organ in the body—the lungs, liver, spleen, serous cavities, joints, and connective tissues—may thus become the seat of fresh purulent collections. The pus from such metastatic abscesses contains the same forms of micro-organism as are present in the wound or other source of infection. Rosenbach (quoted by Senn) has detected streptococcus pyogenes and occasionally staphylococci in the pus and in the blood of pyæmic patients. Besser, of St. Petersburg, has made similar observations, and Schüller has found streptococci in metastatic abscesses in the joints in cases of puerperal pyæmia.

Infection may occur at any time in any septic (and suppurating) wound, though most generally met with in wounds or other injuries which implicate the medulla of bone or in which blood-vessels (veins) are punctured by bony spicula. Pyæmic invasion may or may not be preceded by a brief period of feverishness; but its onset is usually announced by a severe rigor, quickly followed by a marked rise in bodily heat,—103° to 108° F. The rigors recur at irregular intervals, and the temperature undergoes wide and abrupt variations, rising or falling five or six degrees in a few hours. The wound assumes an unhealthy appearance, its edges are œdematous, the granulations become pale and shrivelled, and the discharge is offensive. The pulse soon becomes frequent and feeble, the tongue is red, dry, and glazed, and the teeth are covered with sordes; the skin is icteric, bathed in clammy perspiration, and exhales a sweetish, sickening odor; respiration is hurried, tremulous, and irregular, and a peculiar watchful delirium is present. At about the end of the first week of illness, purulent (metastatic) collections appear in different parts of the body, unpreceded by the usual local evidences of phlegmonous inflammation. A slight degree of redness and swelling appears in the skin, or a joint becomes distended by effusion; a rapid formation of pus follows, and the resulting embolic abscess, when opened, discharges a quantity of dirty, grumous pus, loaded with débris of broken-down connective tissue, and swarming with micro-organisms. Low, muttering delirium takes the place of the previous vigilant form, bloody discharges occur from the bowels, extensive bed-sores or sloughs form wherever there is pressure, the body wastes with fearful rapidity, and the patient dies of exhaustion by the end of the second or the early part of the third week.

Pathology.—The chief post-mortem appearances are purulent collections or embolic abscesses disseminated throughout various portions of the body,—in the joints, in the serous cavities, and in any or all of the viscera,—petechial spots beneath the skin and serous membranes, disintegration of the blood, and a marked tendency to early and rapid decomposition.

Treatment.—Pyæmia is a malignant sepsis, and, in acute cases, all its processes tend to a fatal result. The treatment must therefore be directed to prevention rather than to cure. Pure air, proper hygienic conditions, and a rigidly antiseptic treatment of the wound consequently become important prophylactic measures. When the disease is fairly established, little can be done to counteract the lethal tendency. The treatment must be supporting and stimulating throughout. If, however, the disease is recognized early, it will generally be proper to precede the adoption of the supporting treatment by a moderately active mercurial catharsis by full and repeated doses of calomel. Used early and given in positive doses, so as not only to purge, but also to deplete mildly, this measure in my hands has seemed to control dangerous symptoms and to avert morbid processes which threatened to be very destructive. If possible, the wound should be rendered aseptic by the plentiful use of detergents; free escape must be provided for future effusions, and its surfaces must be protected from further infection. Abscesses, whether involving the joints or other accessible portions of the body, should be opened, drained, and treated antiseptically as soon as detected. No possible good can arise from the presence of the retained pus, and unless speedily evacuated it has a marked tendency to burrow widely beneath the fascia and along the intermuscular planes, and thus adds to the constitutional distress. When a joint is involved, it should be freely opened on both sides, drainage-tubes should be inserted, and the limb rendered immovable by a fixed dressing. Internally, quinine in full doses, with sulphurous acid, salicylic acid, and the hyposulphites of sodium and lime, is worthy of trial. Nutritious broths, milk, and wine are indispensable. The patient must be kept alive as long as possible, in the hope that he may survive the activity of the attack and eventually eliminate the poison.

ANÆSTHETICS AND ANÆSTHESIA.[1]

By OSCAR H. ALLIS, M.D.

THE terms "anæsthetics" and "anæsthesia" are both from the Greek *α*, privative, and *αἰσθάνομαι*, "to feel." The former has reference to the agent that deprives of feeling, the latter to the condition of the patient or animal under the influence of such agent. It is plain that the subject has a wide range and includes all agents that have either a local or a constitutional anæsthetic effect. The present article will be restricted to the consideration of ether and chloroform and their employment for the relief of pain in surgical operations.

Ether.—In the year 1540, Valerius Cordus described the method of making ether. I have seen no mention of the discoverer. It is thought that the drug was known to Raymond Lully two centuries earlier. In 1730, Frobenius first brought it prominently before the medical and scientific world and gave to it the name of ether. In 1795, Richard Pearson employed the vapor of ether in allaying pulmonary distress. In 1799, Sir Humphry Davy, writing of nitrous oxide, said, "it will probably be used with advantage during surgical operations in which no great effusion of blood takes place." In 1818, Faraday published a brief notice of it, in which he alluded to its anæsthetic effect, but with a caution, that was no doubt accepted and promulgated in medical schools.

The knowledge of the fact that physicians had recommended it for a long time for spasmodic pulmonary affections, no doubt led drug clerks to familiarize themselves with its effects, and, strange to say, just prior to its more general introduction it was purchased and inhaled by riotous youth for its exhilarating effects. Being familiar with this fact, and knowing that a negro boy had recovered from an hour of deep sleep and total unconsciousness from its use, Dr. C. L. Long, of Georgia, turned his knowledge of the effects of ether to a practical use by administering it to a patient for the purpose of removing a tumor from the neck. Success was complete, and other patients were induced to inhale the drug for the same purpose and with similar results. This occurred in 1842, and had Dr. Long realized the value of his discovery and given it to the world his name would have been bright in the galaxy of imperishable names.[1]

---

[1] Many diseases are almost peculiar to infancy and early childhood, and when they occur in adult life the experience derived from their study in childhood is turned to the advantage of the adult. In regard to anæsthetics the reverse obtains. What we know of their clinical effects and dangers is derived chiefly from their employment in adult life. If we compare the surgical maladies and accidents of childhood with those of adult life, we shall find that the demand for anæsthetics in the latter is much more frequent than in the former. In the limited space allotted this subject, I shall treat first of matters of general interest, adding from time to time that which is peculiar to infancy and childhood.

A little later (1844), Horace Wells, a Hartford dentist, was present at a public exhibition of the effects of laughing-gas upon persons to whom it was administered. Recognizing its benumbing effect, he on the following day requested Mr. Colton, the lecturer, to administer it to him while he had a tooth extracted. This was done, and Mr. Wells, having felt no pain, turned his experience to the advantage of his patients. Having satisfied himself of its value in dentistry, he believed that its application could be extended to surgery, and offered to give a practical demonstration before the medical students of Harvard. During the extraction of a tooth the patient screamed, though on recovering consciousness he confessed that he had experienced no pain. The result must have been extremely mortifying to Mr. Wells, for he seems from that moment to have lost confidence in the entire project.

The work of Mr. Wells had, however, its good effect, for a student of his, W. T. G. Morton, no doubt relating the experiments of his preceptor to Charles T. Jackson, a distinguished chemist, was induced by a suggestion of the latter to make trials with ether. Full of ardor, he went home to inhale it himself, and soon after extracted a tooth from a patient under its influence. On the 16th of October, 1846, Morton etherized a patient in the Massachusetts General Hospital, from whom Dr. J. C. Warren removed painlessly a tumor of the neck. Thus was given to the world the first practical demonstration of the value of ether as an anæsthetic in surgery.

Chloroform was discovered in 1831 by Samuel Guthrie, of Sackett's Harbor, New York. In 1834 its chemical formula, from which it derives its name,—viz., per*chlor*ide of *form*yl,—was made known. Its value in medicine was early recognized by Prof. Ives, of New Haven, who employed it (in 1832) for the relief of pulmonary spasm. Its anæsthetic effect upon animals was first pointed out by Flourens; and when the news of the great American discovery reached Europe, J. Y. Simpson, at the suggestion of Waldie, took up the clinical study of chloroform, and, carefully noting its effect in fifty cases, gave his results to the world. Thus Simpson's name will always be associated with chloroform, as Morton's with ether.

At the outset there bade fair to be a decided rivalry between the two anæsthetics. European surgeons early adopted chloroform, and still adhere to it, in spite of the hundreds of sudden deaths that have followed its administration. Ether, first introduced in Boston, has never had a rival in that city, and, with the exception of Prof. Gross, the prominent surgeons of Philadelphia and New York have always maintained a marked preference for ether. In the South and West there always has been a decided preference for chloroform, and such was also the case in the armies during the late war. During the last ten or fifteen years of his life Prof. Gross relied principally upon ether, and now in all the medical schools and hospitals of this city chloroform is rarely administered.

---

[1] J. Marion Sims, in Virginia Medical Monthly, May, 1877.

My experience with anæsthetics began with my appointment as interne to the Philadelphia Hospital. On completing my service I was placed on the clinical staff of Jefferson Medical College and given in charge of the chloroform. At the time of which I write, the surgical clinics were divided between S. D. Gross, Professor of Surgery, and Joseph Pancoast, Professor of Anatomy. The former almost invariably employed chloroform, the latter ether: thus the students had an opportunity during their course of study of watching the effects of the two agents upon hundreds of cases.

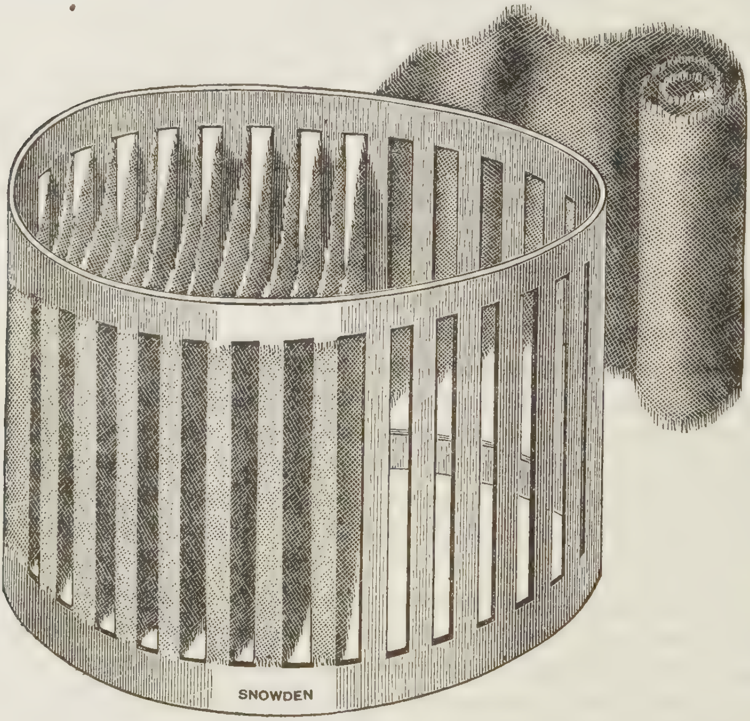
Of all the circumstances under which an anæsthetic may be administered, none is more trying than a public clinic,—trying to the one to whom it is administered, and trying to him who administers it. The former is denied the advantage of a quiet room with all undue excitement removed; the latter is expected as if by magic to have his patient fully anæsthetized the moment the operator is ready. Embarrassing delays frequently occur, and when these are met by reckless haste dangerous symptoms often arise.

I often wondered during my student days, and for years afterwards, why Prof. Gross employed a drug that was manifestly so dangerous,—for many hair-breadth escapes from death were witnessed by every medical class,—and only recently have I struck, as I think, upon the true solution of the mystery. In "The Principles of Surgery" Prof. Gross says, "I have never seen alarming symptoms but in three cases." Alarming symptoms seldom occurred in his private surgical practice,—at least I never saw him exhibit alarm in a private case. This was my own experience, and it is confirmed by others who assisted him for years. Prof. Gross was a teacher. He knew that the only safety in administering chloroform was in vigilance, and to impress this upon his class he took advantage of and magnified every seeming danger.

On retiring from the college service I made a comparative clinical study of chloroform and ether. Procuring a small graduated bottle with dropper, I found that constitutional effects could usually be obtained with twenty drops of chloroform, and artificial sleep with thirty. To secure the value of every drop, I used a small tin funnel, which conveyed the chloroform upon a diaphragm of muslin, from which it was instantly liberated; but when I attempted to produce anæsthesia with this contrivance and ether, I failed utterly. Patients would say, "Pour it on faster," and when inhaling it myself I found that I made no progress. I thus learned, what ampler experience has confirmed, that to produce anæsthesia quickly with ether a large amount of ether vapor must be rapidly liberated. A sponge permits of a large surface for the evolution of ether, and could not be improved upon were it not that many of its loculi or cells are so small that the tendency is to keep the ether in its fluid state. To obviate this, I passed a bandage about three inches wide back and forth between the wires of a frame, and thus gained a large surface upon which a stratum of ether would be in contact with the air. I add below a description of the instrument which I presented to the medical profession in an article published in the *Philadelphia Medical Times*, October 14, 1874. I had no idea that the inhaler would ever come into general use, and I merely introduced it at that time to illustrate better the proper method of administering ether. Its very great popularity is my only excuse for introducing both it and the rules I then formulated for its use.

Description of the Inhaler.—It consists (Fig. 1) of a metallic frame, sufficiently large to cover the lower part of the face. The bars are nearly a quarter of an inch broad, leaving a quarter of an inch between each and its fellow. The spaces are made by a punch, which removes a section from a solid sheet of metal. It will thus be seen that there can be no danger of the bars giving way, as they would were they soldered upon a band.

Fig. 1.



Upon the left a bandage will be seen passed to and fro from bar to bar, dividing the instrument into parallel sections. This will be better understood by comparing Fig. 1 with Fig. 2.

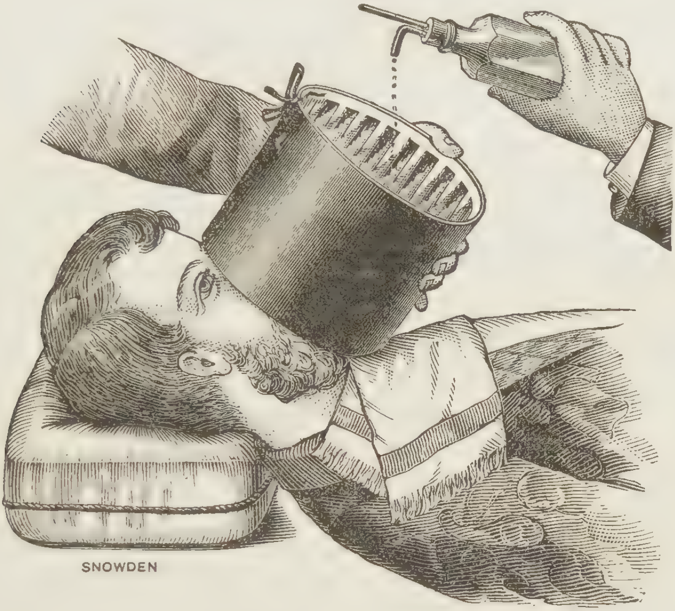
The instrument is then completed by encasing in a leather hood (Fig. 2). I do not think the hood is any advantage, and much prefer a folded newspaper constructed to take its place. After using, the hood should invariably be removed.

The advantages of this mode of construction are,—

1st. It gives the patient (Fig. 2) the freest access of air. It is a mistake to think that air must be excluded. All that is necessary is that *the air should be saturated with the vapor of ether.*

2d. It affords a series of thin surfaces upon which the ether can be poured, and from which it will almost instantly evaporate. In this respect it differs from the sponge, which retains the ether in a fluid state much longer. Should the bandage become soiled, a new one can be inserted in a few minutes.

FIG. 2.



3d. By leaving the instrument open at the top the supply can be kept up constantly, if desired; and, as *ether vapor is heavier* than air, there is no loss by not covering it. The top should never be covered.

Mode of using the Inhaler.—1st. Place a towel beneath the chin of the patient, as experience has taught that a towel should always be within reach in administering anæsthetics.

2d. Place the instrument over the face, covering the nose and chin, and let the patient breathe through it before any ether is applied. This will convince him that he is not to be deprived of air.

3d. Begin with, literally, a few drops of ether: this will not irritate the larynx. Add, in a few seconds, a few drops more, and as soon as the patient is tolerant of the vapor increase it gradually to its fullest effect.

4th. When the patient is fully influenced, it is well to add a few drops at short intervals, and thus keep up a gradual anæsthetic effect.

The Advantages of the Inhaler.—1st. It presents a large surface for the liberation of ether vapor. The partitions are made of thin bandage, and the air coming to both sides of each layer sets the ether vapor free more rapidly than is possible in the use of a towel or sponge.

2d. It is open at the top, and the ether can be added *constantly*, if desired, and in small quantities without removing from the face. The sponge and towel both require removal, and the ether is usually poured on them in quantities.

3d. The ether vapor falls by its weight, as it is heavier than the air; and as the instrument fits the face the patient gets the full advantage of it.

4th. It does not cover the patient's eyes,—does not terrify him, and he often passes under its influence without a struggle.

> 5th. By its proper use the laryngeal irritation may be wholly avoided, the anæsthetic effect will be as easily gained as is possible with the use of ether, there will be a great economy of ether, and great comfort will be secured to the patient.[1]

With this I could in the average case produce anæsthesia in from five to ten minutes, but it required from ten to twelve times as much ether in bulk as of chloroform. It will be noticed that I did not employ any apparatus by which I could measure absolutely the quantity of the anæsthetic inhaled, or graduate its strength. Still, allowing for waste, I found that I could accomplish full and complete anæsthesia with as small a relative quantity as was claimed for scientific inhalers, and as speedily. The full effect of chloroform could often be gained in from three to six minutes, and usually with less than a drachm, and nothing better than a single layer of a towel or napkin could be desired. With ether the chief difficulty was to produce ether vapor rapidly enough, and I occasionally found cases which the most concentrated vapor would but partially anæsthetize.

Every surgeon has been annoyed by the tardy effects of ether, and would have abandoned it for chloroform were the latter as safe. To render chloroform safe and ether more effective a great variety of inhalers have been invented by the medical profession; but it should ever be borne in mind that safety, the great desideratum, does not lie in inhalers. Through their use it has been found that only a five-per-cent. admixture of chloroform with atmospheric air can safely be employed, and yet death has followed the use of this safe quantity in a Snow's inhaler. The pertinent query is, if a five-per-cent. admixture will produce such profound anæsthesia as to permit of a capital operation without reflex manifestations, will not the thoughtless continuance of the vapor produce coma and death?[2] It is possible with the use of a scientific inhaler to know just how much of the anæsthetic has been taken, but no instrument has ever yet been contrived to measure the effect upon the patient.

When chloroform is administered on a towel, the latter is usually folded into eight layers. Some teach that "it is not necessary to begin with more than a drachm," while others recommend enough to moisten the towel for a space about the size of the palm, the precise quantity used being a matter of no consequence whatever. How such instructions are consistent with safety I do not understand. In all such administrations there is a needless waste if the towel is held at a distance from the face, and a criminal recklessness if it is held close to the face. Instead of taking a folded towel, I take but a single layer, and then if I drop on more than is necessary it is promptly dissipated. With a single layer there can be no retention of the anæsthetic, and hence it must be constantly renewed. I do not think I am over-confident when I state that one thousand administrations of chloroform, without distinction as to age or sex, could be accomplished with less than one thousand drachms of the drug, and in each instance a degree of anæsthesia be obtained sufficient for the inception of the gravest surgical undertaking. A few large, powerful adults might require more than a drachm, but in the majority of men and women and invariably in children the amount would be less. When I administer chloroform and accomplish the desired effect in four minutes, when I consider that in this time there have probably been but sixty full respirations and that I have used but sixty minims of chloroform, then it is that I realize the value of a minim of the agent; and I cannot but dread the dissemination of a doctrine that would dispel all fears of its deadly action. Scores of witnesses have declared that death occurred after a fresh supply of chloroform was put upon the towel, and, for one, I do not doubt that in persons fully anæsthetized a single deep inspiration from a saturated towel has produced death, since a single minim properly administered has definite anæsthetic value.

---

[1] Dr. George R. Fowler published in *The Medical Record*, July 2, 1887, the description of an instrument to which he has given the name of "A Folding Allis's Ether Inhaler." It is constructed on the principle of Fig. 1, but is square instead of oval. When packed for transportation it is nearly flat. Space will not permit of an illustration.

[2] Holmes and Hulke, vol. iii. p. 598.

I have but little to say in regard to the administration of ether. In most cases there will be no difficulty in administering it upon a folded or funnel-shaped towel or sponge. Unlike chloroform, the ether should be sprinkled on freely, but, as with chloroform, it is better to sprinkle it on at short intervals than to saturate the towel. If the administrator watches his opportunity he can sprinkle on fresh ether in the interval between expiration and inspiration, and thus not lose a single inhalation. In some instances the vapor is irritating to the larynx. In such cases it is humane, to say the least, and a saving of time, to suspend the administration and permit the patient to take one or two deep inhalations of pure air.

With females and with most men anæsthesia can be readily accomplished with ether. But it occasionally happens, as I have already intimated, with children as well as with adults, that ether seems to have scarcely any anæsthetic effect. The difficulty with this class is, they do not breathe; *i.e.*, their breathing is so shallow that the minimum of respired air consistent with comfort is inhaled. This class will be no more under its influence in ten minutes than after the first inhalation. To produce anæsthesia in them with ether, resolute, determined action is necessary. They must be compelled to breathe, and to breathe deeply. The towel or sponge being fully saturated with ether, hold it a little above the mouth and nose, but so tightly about the face that no air that is not saturated with ether can be respired. As soon as this is done, a struggle for supremacy will begin, for which the anæsthetist must be prepared. With the struggles come deep respirations, and often in a single minute the struggles cease, the characteristic deep respirations of beginning etherization are heard, and the victory is complete. As soon as the deep respirations are noticed and the struggling abated, the ether must be administered with more care. It is only to overcome, to gain the mastery, that such measures are at times required, and as soon as the mastery is obtained the further effect must be continued as in other cases. It will be asked, "Is it safe to administer ether in this manner? Is there no danger of suffocation? Have not persons been suffocated in this way?" I answer, I have never witnessed a single alarming symptom, nor a single case in which following this struggle for supremacy it was necessary to discontinue the ether and resort to efforts at resuscitation. Ether administered in this way—or, in fact, in any way—must be administered with judgment: the effect must be watched, and when the effect is gained, no matter how, or how quickly, no intelligent or watchful administrator will increase its influence.

Some physicians, annoyed by the frequent delays of ether, and unwilling to incur the risks of pure chloroform, have thought to improve upon both by mixing them. A mixture of one part of chloroform and two parts of ether was at one time extensively used, but has been abandoned as unsafe. For my part, I consider it far more dangerous than pure chloroform, and the reason why I so fear it is that it is regarded as being as safe as ether while it has five times the latter's anæsthetic potency.

In many cases, and almost invariably with children, I begin with chloroform, and, having gained the first anæsthetic effect, transfer the patient to my assistant, who administers ether.

Whatever anæsthetic is employed, as soon as the requisite degree of anæsthesia is obtained, the effect should not be increased, but should be steadily maintained by a constant supply of the minimum quantity possible. To establish and maintain complete anæsthesia—neither carrying the patient beyond the limit of safety nor suffering him to return to partial consciousness—is an accomplishment worthy the ambition of every practitioner of medicine and surgery.

In the administration of anæsthetics to children the same series of phenomena are noticed that occur in adults. The majority of children cry and struggle after the first few seconds, and, as this is attended with deep and rapid inspirations, the anæsthetic effect is, as a rule, rapidly obtained. The struggling imperatively demands a strong and resolute assistant, one who is familiar with the effects of the agent and whose sympathies are not a matter of sentiment. In many instances the anæsthetic irritates the bronchial mucous membrane. Mucus is poured out rapidly and in large quantities throughout the entire bronchial tract, and often to a distressing degree, respiration is embarrassed and accompanied with large moist râles, the lips become livid, the face is cyanosed, and all the signs of non-oxygenation of the blood are present. Under these circumstances the only relief the little sufferer obtains is from incessant spasmodic coughing. To withdraw the anæsthetic entirely in such cases while a painful surgical operation is in progress is manifestly undesirable, but prudence will hold the anæsthetic effect on the confines of consciousness. I have often witnessed this condition, and believe it to be a more frequent accompaniment of ether than of chloroform. I have never witnessed any serious results from this condition.

Although I have stated that the majority of children resist the administration of anæsthetics, my own experience is that the opposition to ether is much more decided than to chloroform. In cases where I have been required to complete a painful surgical procedure, I have had the little patient plead for chloroform, especially if it has once experienced its effects. The question often arises, can a person be put under the influence of an anæsthetic during sleep? I cannot speak from experience with ether, or in adults, but I am positive that chloroform can be administered to a sleeping child without its waking to consciousness.

Although chloroform is dreaded by the profession generally, the popular verdict being manslaughter when a death occurs from its administration, still my decided preference in every case, and especially in children, is for that anæsthetic. When I say especially in children, I do not wish to be understood as endorsing the oft-repeated assertion that "you cannot kill a child with chloroform." The supposed immunity enjoyed by children is not borne out by statistics or clinical practice. Deaths have occurred in early life, and would be more frequent were operations as common in childhood as in adult life. The real source of safety is the chloroformist's instinctive caution. I shall never forget the mortification I felt, when in charge of the anæsthetic in the clinic of the elder Gross, at not being allowed to administer to an infant that was about to be operated upon. In this instance Dr. F. F. Maury, the chief clinical assistant, took a single layer of a towel and, cautiously sprinkling on a few drops of chloroform, shook it, to guard against excess, and then held it first at a distance from the infant's face, to avoid frightening it, and, gradually bringing the agent nearer the face, as the little patient became accustomed to it, soon obtained the desired effect. Wherein, I ask, lay the safety in this single instance? and the ready response will be, "In the cautious administration." In marked contrast to this were the haste, precipitancy, and I might almost say recklessness with which at times it was given to adults. Only a few clinics previous to the one mentioned, I was administering chloroform to a consumptive female from whom a tumor was to be removed, and, as she came slowly under its influence, Dr. Maury took the two-pound bottle of chloroform and dashed on, possibly, a half-ounce. The effect was decidedly too great, and but for the timely and energetic action of Prof. Gross, whose quick perception took in the situation, a fatal issue might have been the result. Wherein lay the danger in this case? Certainly not in the chloroform, but in its maladministration.

When, however, I commend chloroform, I always do so on the sole condition that it shall be properly administered. Unless the anæsthetist can be made to realize that each minim of chloroform has positive anæsthetic value, and unless he can devote his entire attention to the condition of the patient, he is unfit to handle it; and for this reason, and no other, I endorse the popular verdict that ether is the safer anæsthetic.

It occasionally happens that an infant requires an anæsthetic within a few hours after birth. Clinical experience has shown that so grave an operation as a laparotomy or a herniotomy can be safely undertaken at this tender age. I have never administered an anæsthetic under these circumstances, but should not hesitate to give either when required. Under such circumstances I should strongly recommend the course of Dr. Maury already referred to,—namely, to add a few drops of chloroform to a single layer of a napkin or handkerchief, and begin the administration by holding it first at a distance of six inches from the face, and gradually approach the face as the first irritating effect passed off.

In membranous or spasmodic laryngitis the administration of, so to speak, an atmosphere of chloroform has in my hands had a magical effect. I have entered the room and found the father carrying his struggling child, cyanosed and gasping for breath, and, following the movements of the father as he walked about the room, have held a little chloroform above the child's face. In a few moments the struggling ceases, the color returns to the lips, the patient becomes quiet, and is in as advantageous a condition for an operation as could be desired. I have heard surgeons, speaking of the imminent danger under these circumstances, declare that there was no time to administer an anæsthetic, and that a moment's delay would have been death. I do not wish to put my own judgment against the experience of any surgeon, but I am strongly of the opinion that spasm is an element of great importance, and often the immediate cause of death.

In a neighboring city a child, while playing with a piece of broken china in its mouth, passed the fragment into the larynx. Physicians were summoned, and while efforts at extraction were made the child was suffocated. The foreign body lay in the larynx, but did not completely close it: had it done so, the child would have died as suddenly as from drowning. As it was, there was time to summon physicians and time for fruitless attempts at extraction. Under such circumstances, chloroform would have made the larynx tolerant of the foreign body until a surgeon could have been obtained, when laryngotomy might have rescued the child from impending death.

Anæsthetics are often administered in early childhood with a view of making a positive diagnosis in hip-disease. The painful nature of the affection often precludes the possibility of handling the joint, and hence a resort to ether or chloroform. Such a procedure for mere purposes of diagnosis I believe to be unwise and unsurgical. After full anæsthesia the fixation of the hip often entirely disappears, and the unwary examiner pronounces the joint sound, and recommends a course of action as unwise as his diagnosis is incorrect.

The elder Gross almost invariably operated upon hare-lip in early infancy without an anæsthetic, and some, fearing lest blood should find its way into the larynx, have in like manner attempted staphylorrhaphy without it; but this course is, I think, seldom followed by surgeons nowadays. For myself, I have never witnessed any unpleasant symptoms from operations within the buccal cavity. Tonsillotomy is usually performed with the consent and co-operation of the patient, but there is no danger in performing it with the child recumbent or semi-recumbent and under the influence of an anæsthetic.

Persons of limited experience in the use of anæsthetics often ask for information on the following points.

1. Is it safe to administer them in cardiac or pulmonary diseases, or to persons suffering from shock or from loss of blood, or prostrated by long and wasting disease? And, if so, which is preferable?

2. Can they be safely administered to the very young and to those of advanced age?

3. How long is it safe to continue the anæsthetic effect at one time?

4. Are repeated administrations prejudicial to health?

5. Have permanent bad effects ever been traced directly to anæsthetics in surgical use?

6. Are there circumstances under which ether is preferable to chloroform, and *vice versa?*

Cardiac disease, though relatively infrequent, is possible in all its phases in infancy and childhood. With the exception of interstitial changes, the accompaniment of advancing years, the child's heart does not differ in its physiological actions from that of the adult. What is true of cardiac is true also of pulmonary affections: every type of disease may be found in infancy and childhood. It behooves the administrator of the anæsthetic to discriminate carefully as to the character, extent, and depressing influence of the disease in question. So, too, in shock, anæmia, prostration from loss of blood, etc. In such conditions the solution of the problem hinges not on the state of the system, but on the urgency and magnitude of a surgical disorder, whose attention imperatively demands an anæsthetic, and without which the surgical procedure would be impossible. When such embarrassing circumstances arise, the only resource lies in the judicious handling of the anæsthetic. For the comfort of the anæsthetist, I will say that death seldom follows the administration under these conditions, the long list of casualties showing no disease whatever to which the fatal result can be attributed.

Under these circumstances, shall ether or chloroform be given? Ether is said to be a cardiac stimulant or excitant. That this is so in the early stage of anæsthetization is of little practical moment. The fact that it is not a prolonged stimulant, the stimulation not continuing after the full effect is obtained, places it practically upon a par with chloroform. Both are cardiac depressants when pushed beyond the proper limit of anæsthesia. In the above-mentioned conditions the majority of surgeons would prefer ether, and when I give an opinion in favor of chloroform I shall be asked to defend it. My reasons therefore are—

1. It requires only *one-tenth* the amount of chloroform to produce the desired effect, and therefore the system does not become so saturated with

it, and there is not subsequently such profound and long-continued nausea and distaste for food.

2. Chloroform is a much more manageable agent than ether. I regard each minim as possessing anæsthetic value. Hence I feel that with it I can control the anæsthetic effect with great precision.

Both these reasons are of the utmost importance when an anæsthetic is to be administered to one in an exceptionally feeble condition.

I have already spoken of anæsthetics in the tender years of infancy, and given detailed instruction upon that head. Man is never twice a child physically. The succulent, elastic, rapidly-developing condition of childhood contrasts strongly with the shrinkage, attenuation, and aridness that are consequent upon old age. Hence the conclusion that, if care is necessary in infancy and youth, it is of fourfold imperativeness in decrepitude.

The length of time that one may safely inhale an anæsthetic will vary with the circumstances of the case. When there is much loss of blood, when the shock, as in amputation of the thigh, is necessarily great, when the patient is almost bloodless at the time the operation is undertaken, then there must be a minimum amount of the anæsthetic, and the greatest possible despatch. Despatch—not reckless haste—is too little appreciated in these days of anæsthesia. I fear there are many victims to what is now boastfully styled deliberation. The pendulum has swung to the other extreme. The time was when students took out their watches to count the seconds of an operation. Now they may go out to lunch, and stroll back to the finish!

As to repeated administrations, they are seldom required in infancy. In childhood and youth they are as well borne as in adult life. I have never witnessed permanent bad effects from the use of chloroform or ether.

Are anæsthetics ever inadmissible? Surgeons who rely upon chloroform use it for nearly everything, just as others employ ether. There are some points that should never be lost sight of. When the cautery is required, do not bring the heavy ether vapor near it. I have seen a conflagration on three occasions, and, strange to say, in every instance it occurred to persons long familiar with the inflammable nature of ether and ether vapor. When the erect posture is required, then use ether, not chloroform. Some fear lest blood may run into the larynx during operations on the mouth and nose. I have never witnessed an alarming symptom from strangulation on these occasions. Vomiting will, of course, follow, but this is a very common occurrence with anæsthetics.

Flagg demonstrated as early as 1848[1] that it was possible to etherize a patient sufficiently for the removal of a scirrhous breast, without reflex manifestations or consciousness of pain, and yet retain a drowsy consciousness of everything passing, and ability to understand and give correct replies to questions asked during the entire operation. The experience of practical surgeons is that the graver the operation the more complete the anæsthesia should be, since there is a corporeal suffering or shock from an operation when too little is administered, that can be greatly lessened by full anæsthesia.

---

[1] Medical Examiner, No. xxxvii., January, 1848; also "Ether and Chloroform," by J. F. B. Flagg, Lindsay & Blakiston.

Packard has availed himself of the first loss of consciousness to open abscesses, reduce a luxation, etc. The patient is told to raise the arm and hold it up while inhaling, and when it becomes unsteady and drops, the abscess is opened, and the patient returns promptly to consciousness. Of course, if a further anæsthetic effect is desired, it can be readily obtained. It requires an experienced surgeon to know when a few seconds will suffice for an operation.

SUGGESTIONS FOR THE ADMINISTRATION OF ANÆSTHETICS.

1. If the patient has taken opiates for the relief of pain, the amount should be carefully inquired into. I have never known any unpleasant effect to occur in infancy or childhood, but I have repeatedly witnessed profound coma, in one instance a narrow escape from death, and in one death, which was clearly the result of the enormous amount of morphine administered after an injury. In these cases the drug was manifestly unabsorbed, owing to the degree of shock and pain, the patient being apparently unaffected by the morphine and calling continually for more, but absorption took place during the exhibition of the anæsthetic, and dangerous and even fatal narcosis followed.

2. The condition of the heart, lungs, and kidneys should be ascertained prior to the operation. All discussions of the safety of administration, etc., should be settled beforehand, not at the time of administration. If this has been neglected, it should be done before administration, as ignorance on this point is unfavorable.

3. The patient, if robust, should be denied food and drink for six hours before inhaling. If feeble, hot beef tea, or peptonized food, should be given an hour before the operation. In infancy and childhood no rules are obeyed. In childhood do not restrict the food, but regulate it. Mushy foods are more easily and safely vomited than meat, apples, and chestnuts.

4. All restrictions in the clothing that will embarrass respiration should be removed. Look to the neck and waist. See that everything is loose: take no patient's word for it.

5. All parts of the body, especially in infancy and in the weak and aged, that do not require exposure should be covered and shielded against cold. This simple injunction is too often disregarded.

6. Always inquire about false teeth. Make a habit of it. It will do no harm to ask the question, even if it be done in sport. Neglect to form the habit may lead to oversight and disaster.

7. Basins and towels should be in readiness before the administration is begun. Vomiting is likely to occur in every case, and not to provide for

it is certainly inexcusable. Vomiting occasionally occurs before the full effect of the anæsthetic is obtained. More frequently it occurs on returning to consciousness. I have often remarked that patients who secreted and swallowed much saliva during the inhalation invariably vomited as the effect was passing off.

8. Forceps, tenaculum, mouth-gag, tongue-depressor, ammonia, brandy, and pounded ice should be placed where they can be reached.

9. The administration should be begun in retirement. No conversation. No busy getting things ready. No fussy doctor to hold the pulse. Assuring words from the administrator in a low tone will act as a diversion and be of advantage.

10. When the patient is fully influenced, and not before, let an assistant hold the pulse. This of all precautions is the least essential; but, if it be required, omit it while the patient is conscious.

11. The working anæsthetic zone is usually preceded by deep, heavy breathing. As soon as this is heard, the desired effect has been reached, and a more profound effect should be guarded against. The administrator should hear every breath, but he should hear nothing else. He should be deaf to all general conversation. Inconsiderate by-standers will ask him questions: these should be rebuked by silence.

12. The effect produced is best known by the character of the breathing. One ear is worth a dozen eyes. Were all anæsthetists blindfolded, there would be fewer deaths.

13. When the eyes are used, let them be used to the advantage of the patient, and not to the advantage of the operator or his assistant. So long as the lips have a healthy color, the capillary circulation is good. When they become livid and the face ashy pale, proceed with caution. Watch the lips,—not the steps of the operation.

14. When the working anæsthetic effect is reached, hold it by repeated additions of a minimum quantity of the anæsthetic.

15. To hear every breath and to keep the patient in a safe but unconscious state demands the fullest attention of the administrator. His sole duty is with the anæsthetic. If the surgeon has failed to supply himself with proper assistance, if an artery spurts and no one is at hand to attend to it, if any emergency arises that could not have been foreseen, leave these with the surgeon. Your duty is wholly with the anæsthetic.

16. When the operation is over and the patient is to be prepared for his bed, do not leave him on any account. Don't abandon the ship as she is entering the harbor. See your patient safely in bed, either fully conscious or in gentle sleep, and leave others to look after other matters.

It is a matter that denotes healthful progress that, in our large cities, a skilled, experienced assistant is usually secured to administer the anæsthetic. Undergraduate medical assistants and nurses are now detailed to duties better suited to their capacities. It is also to be noted that the anæsthetist is now compensated, though meagrely, for his services.

ACCIDENTS FROM ANÆSTHETICS.

An "overdose" often occurs through ignorance or want of attention on the part of the administrator. I attribute the "clean record" of those who have been life-long friends of anæsthetics to their personal vigilance. Prof. Gross never put absolute trust in any assistant.

One of the most alarming symptoms, especially to those who have had little experience, is the sudden stoppage of respiration, as if through closure of the larynx. The patient struggles, becomes livid, but cannot inhale. In such a case, if the tongue is drawn forward and depressed at its base, air will promptly enter the lungs, and all danger will vanish. The danger in these cases is often more apparent than real. It is not always safe to put the finger in the mouth to depress the tongue. The jaws have closed on many a hand with a will that proved that danger was far off.

When the anæsthetic has been pushed too far, when too profound an effect has been obtained, when symptoms of coma or syncope arise, then the danger is far greater. In this condition the tissues are poisoned with the agent: blood, heart, brain, lungs,—all are saturated. For this class Nélaton suggested depression of the head and elevation of the lower part of the trunk, or, as some have termed it, "hanging the patient up by the heels." The rationale of this course is that the blood impinges on the brain, from gravity, and stimulates centres that a feeble or pulseless heart could not reach.

Cold or hot water dashed on the exposed chest, and slapping the chest with a towel dipped in water, either cold or hot, are valuable means for provoking reflex action. Ammonia held near the nostrils acts as a restorative. In severe cases the trachea has been opened and the lungs filled by means of a bellows.[1] Insufflation (mouth to mouth) has, no doubt, proved of advantage in some cases. Venesection in desperate cases has been resorted to.

A study of the accidents, the modes of death, and the efforts at reanimation has led me to put little confidence in restoratives. Most of those resuscitated reacted promptly,—within a few seconds, certainly within a minute or two. I do not think I ever saw dangerous symptoms continue for one whole minute. I have seen the patient profoundly influenced and have watched the effect for many minutes with anxiety, but in all these cases the heart and lungs were still in action. Unless the heart and lungs resume their functions promptly, I believe death always follows. I do not believe a life has been saved by tracheotomy or persistent artificial respiration—by Silvester's or Howard's methods—if five minutes have passed without good results. I make these statements not to discourage any one in the use of restoratives, but—

---

[1] This extreme measure has not been crowned with success, probably because it is delayed until after death has taken place.

First, to warn persons against inattention in giving anæsthetics,—to caution them about carrying their patients beyond prudent limits.

Second, when danger arises, every second is a lifetime : prompt efforts are the only efforts that have ever succeeded.

There is one safeguard, which consists in cutting off by means of a tourniquet the circulation of some part of the body, as, for instance, that of the entire thigh and leg, and keeping this blood free from toxic influences during the operation. When this is over, the tourniquet is removed, fresh, pure blood—as by auto-infusion—seeks the heart and brain, and reanimation is rapid and complete. This precaution has not yet been generally adopted, and no accidents for or against it have been reported. It cannot be urged as necessary if due caution is exercised, but it would be a most timely resource in case of overdose.

PATHOLOGY.

Autopsies have never revealed anything that could justly point to the anæsthetic. The true cause of death in the majority of cases is toxic agency, and this the microscope cannot reveal. A few cases of asphyxia have been demonstrated. Some deaths attributed to anæsthetics are mere coincidences. The "fatty heart" is alleged to be present in most cases, and is the sole comfort of the survivors.

PART IV.

DISEASES OF THE OSSEOUS SYSTEM AND OF THE JOINTS.

CONGENITAL ABNORMALITIES OF THE EXTREMITIES.

By THOMAS R. NEILSON, M.D.

As indicated by its title, this article includes within its scope only certain abnormal conditions of the extremities which either are present in fact, or the tendency to which exists at the time of birth. In the limited space at his disposal, the writer has found it impossible to enter into a purely scientific or teratological discussion of the subject, and has therefore endeavored to deal with its several subdivisions more from a practical point of view.

While a considerable proportion of the instances of congenital abnormalities are of such a nature as to be of little interest to the surgeon except as anatomical or pathological curiosities, there still remain a much greater number which possess a practical interest for him, inasmuch as operative interference or the selection and adjustment of an apparatus may be demanded for their improvement or cure.

The origin and causes of malformations afford a fertile field for investigation. The obstacles to pursuing systematically such a study are, of course, very great, but, through the aid of our knowledge of embryology and comparative anatomy, many of them have been overcome. In early times, when superstitions of all kinds ran rife, it is not to be wondered at that deformities or monstrosities were attributed to such causes as judgments or visitations from the Creator, the wrath of heathen gods, or the evil influences of witches. A theory which has long existed, and which has still many adherents in the profession as well as among the laity, is that in some cases these deformities result from a profound impression made upon the mother's mind during gestation,—maternal impressions. In regard to this, while it is very obvious that through the influence of mental or nervous shock to the mother the general condition of the fœtus may suffer, and even its death ensue, there is no ground, other than pure theory, for assuming that because the mother has been shocked by the appearance of a malformed member belonging to some individual whom she may have encountered, she will give birth to a child similarly malformed. In many cases, if the circumstances be inquired into, it will be found that the occurrence of such a shock took place at a period too late in the development of the fœtus for it to have had the influence attributed to it; and nearly always it is recollected or spoken of *after* the birth of the child and the discovery of the existence of an abnormality. In many instances, too, the likeness of the deformity to the object which produced the shock in the mother is purely fanciful, and fades into nothingness before a careful examination of the part.

The origin of all congenital deformities will be found to fall under one or other of the four following heads:

1. Excess of development,—including supernumerary limbs and digits.
2. Arrest of development,—whole or partial absence of extremities.
3. Mechanical injuries by amniotic bands and the umbilical cord,—distortions of the extremities (club-hand and club-foot) and intra-uterine amputations.
4. Original fault in the germ, either ovum or spermatozoön,—hereditary malformations.

CONGENITAL HYPERTROPHY OF THE EXTREMITIES.

This must be classed as a comparatively rare abnormality. It consists in an excessive growth of all the parts which make up an extremity. The affection is usually unilateral, one extremity alone, or part of it (and in this case its lower end), being involved. The fingers and toes, in fact, afford the most numerous examples. The subject has engaged the attention of various writers from time to time, contributions to its literature having been made by Trélat and Monod,[1] Battersly,[2] and others, and more recently by Anderson.[3]

The origin of the condition cannot be certainly stated, nor can it be always asserted, save when the digits are affected, that it is present in any marked degree at the time of birth. It seems probable that the cause lies in an affection of the nerve-centres governing the nutrition and development of the part; but this has not been demonstrated. Heredity has nothing to do with it.

The disease is progressive, sometimes rapidly so, and, as has been said, implicates all the normal structures of the member. The bones are enlarged, markedly so at the epiphyses; the ligaments are increased in thickness; the muscles and tendons are excessively developed; and as to the blood-vessels, while the arteries may not be affected to a noticeable degree, the occurrence of varicose veins and angeiomata is frequent; the lymphatics are said to be prone to dilatation; the nerves do not appear to be altered. The subcutaneous fat is increased in thickness, lipomatous tumors being quite common in hypertrophied limbs. The disease is usually painless. The temperature of the limb is generally unaffected, but cases have been reported by Reid[1] and by Trélat and Monod (*loc. cit.*) in which it was somewhat above the normal. The degree of mobility and usefulness of the limb varies: in some cases it is quite good, in others moderately restricted, and in still others the part is entirely useless. Fingers and toes, when affected to any considerable extent, are apt to be distorted or bent in one direction or another, usually laterally or backward, the distortion being explained by Curling as due to tension of the displaced extensor tendons which have not elongated proportionately to the length of the digit.

---

[2] Dublin Medical Press, vol. xxiii.

[3] St. Thomas's Hospital Reports for 1881.

Although the deformity is usually unilateral, cases have been recorded by Curling[2] and by Annandale[3] in which it was bilateral. In these instances, however, it was limited to the digits, the remainder of the limbs being normal.

The degree which the hypertrophy may attain is exemplified in the two following cases. In the first case, reported by Dr. William Osler,[4] the right upper extremity was affected.

The patient was a girl eight years of age. Comparative measurements showed the following excesses in favor of the affected limb: half of chest, four centimetres larger; humerus, three and one-tenth centimetres longer; circumference of arm at biceps, extended, two and nine-tenths, flexed, four and four-tenths centimetres greater; forearm, four and two-tenths centimetres; wrist, three and five-tenths centimetres; hand, four and six-tenths centimetres; middle finger, five millimetres; index finger, seven millimetres. The muscles of the arm, especially the biceps, were well developed, as were also those of the forearm, and the muscular power of the limb was greatly increased. The wrist was thick, the hand square, thick, and short, the fingers small in proportion, and kept strongly flexed, all but the middle one having the motion of extension.

In the other case, recorded by Dr. T. W. Hurley,[5] the malformation was limited to three digits,—the thumb and the index and middle fingers of the right hand.

The patient, a child thirteen years old, exhibited at the time of birth some enlargement of the affected fingers, and their relative size had continually increased up to the time of observation, when the measurements were found to be as follows: index finger, seven inches in length, five and three-fourths inches in circumference; middle finger, nine inches long, and about the same in circumference as the index; thumb proportionately enlarged. The diseased digits were amputated, and their condition was shown to be due to an affection—"obliteration"—of their lymph-channels.

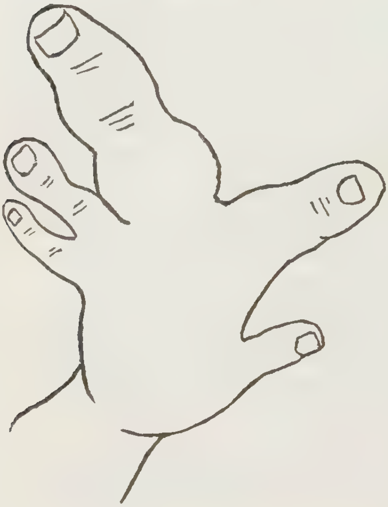
Fig. 1, from Annandale, shows an instance in which the middle and index fingers were hypertrophied, the patient being a child three years of age, and the deformity having been noticed at birth.

FIG. 1.



(After Annandale.)

True hypertrophy must be distinguished from an increase in the size of a member due to excessive growth of its cellular and adipose tissues. In the latter the muscular, ligamentous, and osseous structures are unaffected.

Treatment.—Where a whole limb is hypertrophied, the prospect of benefit from treatment is not encouraging. Pressure has been tried, but usually without success. Mr. Holmes, however, in his "System of Surgery," mentions one instance in which the persistent use of an elastic stocking was followed by a diminution in the size of an hypertrophied leg. When the lower extremity is affected, and active interference does not seem to be called for, the increase in length of the hypertrophied limb over that of the normal one should be compensated for by the use of a thick-soled and high-heeled boot upon the latter. In either extremity, if the disease progresses to such an extent as to render the member useless or a burden to the individual, or if, contrary to the general rule, there be persistent and unbearable pain, the case will be one for operation.

The first resource lies in ligating the main artery of the limb. Mr. Christopher Heath[1] has reported a case of hypertrophy of the leg successfully treated by ligature of the external iliac artery. If the deformity be of an extreme degree, it is not likely that this operation will be rewarded with success, and the only resource is amputation.

For hypertrophied fingers and toes the only treatment to be recommended is amputation, care being taken to remove along with them the heads of the metacarpal or metatarsal bones if they are involved in the affection. Care must also be taken that the operation does no damage to the neighboring normal digits. If it be impossible to remove the affected digits without inflicting injury upon the healthy ones, the operation should not be undertaken.

---

CONGENITAL DEFICIENCIES.

The class of malformations included under this head is by no means a small one, and includes defects of development varying in extent from the absence of a portion of a single digit to the lack of one or more entire limbs. While often confined to one extremity, the deficiency is not seldom observed to be bilateral, and cases are recorded in which all the extremities of the individual have exhibited some failure of development, and in at least two recorded instances, one reported by Hardy[1] and one by Hare,[2] both upper and both lower extremities were entirely wanting. Cases in which both upper extremities were absent have been met with by T. Smith,[3] by Ramon,[4] by Gee,[5] and by Curran.[6] Barwell[7] reports two cases in which both arms were truncated and bore upon their ends rudimentary hands.

In his comprehensive work entitled "Histoire générale et particulière des Anomalies de l'Organisation chez l'Homme et les Animaux" (Bruxelles, 1837), Isidore Geoffroy Saint-Hilaire has divided malformations of the extremities due to defect into three classes:

1. "Ectromélie" (from the Greek ἔκτρωμα, "an abortion," and μέλος, "a member"), the condition in which the extremities, either upper or lower, are entirely absent or nearly so. The term applies only to cases in which the deficiency is the result of arrest of development, not to intra-uterine amputations. Individuals thus deformed are designated "ectromèles."

2. "Hémimélie" (ἥμισυς, "half," and μέλος), the condition in which the limbs are very incomplete, terminating as stumps, and possessing either no digits or very imperfect ones. Persons presenting this abnormality are called "hémimèles."

3. "Phocomélie" (φώκη, "a seal," and μέλος), the monstrosity in which the limbs are absent and the hands and feet are joined immediately to the trunk, the subjects of the deformity being named "phocomèles."

A considerable number of instances of partial deficiency—*i.e.*, the absence of one or more bones, or portions of them, of the upper extremity—are to be found in the literature of the subject. Cases in which the radius was absent have been reported by Swaagman (double),[8] Ledru (double),[9] Letulle,[10] Hodge,[11] Gruber,[12] Erichsen,[13] Parker (one case double, another double with double deficiency of tibia),[1] and others. The ulna is much less frequently missing, the only cases that have been met with in my search being reported by Schnelle,[2] Senftleben,[3] and A. Sydney Roberts,[4]—one each. Defects of the bones of the forearm are usually associated with a deformed condition of the hand, diminution of the number of fingers and metacarpal bones being most common, and when the radius is the deficient bone the condition known as club-hand is apt to be present.

[12] Archiv f. Path. Anat., 1865, vol. xxxi.

[13] London Lancet, 1858, vol. i.

As to the bones of the lower extremity, a case of entire deficiency of both femora has been recorded by Williams,[5] and instances where it was in a rudimentary state are reported by Ehrlich [6] and Hirst.[7] Deficiency of the tibia has been observed, so far as I know, in thirteen recorded instances. J. K. Young [8] reports an interesting case, in which the defect was bilateral (complete upon one side and partial on the other), and mentions eleven other cases which he had gathered from the literature of the subject, the observers being Billroth, Albert (two cases), Myersohn, Pauli, Parker, Ehrlich (three cases), Thümmel, and Busachi. In three of these the defect was bilateral, completely so in two of the three. W. Henry White [9] reports the last case to which I find reference. It is an instance of complete bilateral absence of the bone associated with deficiency of the condyles of the femora, and with defects in both hands, the right one having only the thumb and the little finger (the other fingers and their metacarpal bones being missing), and the left having the thumb and the index and little finger (the ring finger and its metacarpal bone, and the middle finger, though not its metacarpal bone, being wanting). Thus, then, of the thirteen cases of tibial defect, in five the condition was bilateral—complete in three—and unilateral in eight.

In all these instances the fibulæ of the deformed limbs were shorter than normal, and the feet are without exception reported as being in a position of more or less extreme varus.

Deficiency of the fibula has been met with somewhat more frequently than the last-named deformity. Eighteen cases were collected by Myersohn,[10] and more recently two have been reported by Gould,[11] and one by Brothers and Pope,[12] associated in each instance with absence of two toes and diminution in the number of metatarsal bones, and being unilateral, the foot in one of Gould's cases being turned outward, while in the other it was in the position of equino-varus.

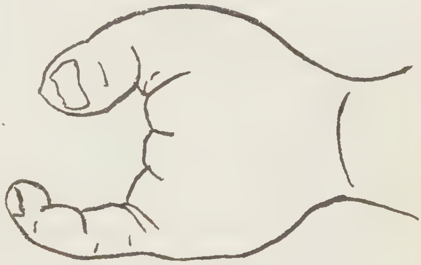
As in the case of the upper extremity, deficiencies in the bones of the lower extremity are usually associated with a defective or deformed condition of the distal segment of the member, and thus with any of the foregoing there may be observed a diminution in the number, and a faulty position, of the bones of the tarsus and metatarsus, and absence of one or more toes.

Deficiencies of the fingers and deficiencies of the toes are so similar in many respects that they may be spoken of together.

There may be a diminution either in the number of the digits or in the size or the number of their segments; and sometimes, in addition to the absence of certain digits, those which are present will be observed to be smaller than normal, and to be lacking in the number of phalanges.

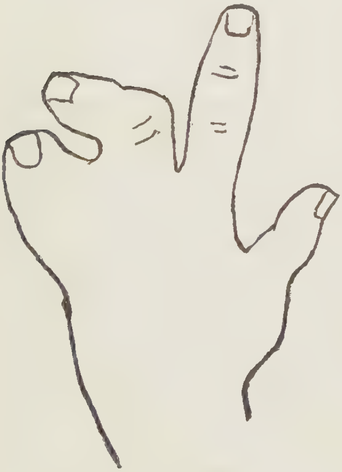
FIG. 2.



(After Annandale.)

Fig. 2, from Annandale (*loc. cit.*), represents the hand of a girl, four and a half years old, which lacked the index, middle, and ring fingers, and the metacarpal bones of the two former. The thumb was double, there being two first phalangeal bones. The two digits which were present were perfectly movable and useful for purposes of prehension.

FIG. 3.



(After Annandale.)

Fusion of two or more digits may occasion an apparent deficiency in development. Fig. 3, from Annandale, is from such a case, the patient being a child sixteen months old, the hand having apparently but three fingers, the ring finger being absent and the middle and little fingers webbed. Careful examination showed that the first phalanx of the ring finger lay obliquely in the web between the middle and little fingers, and that the other two phalanges were united to the corresponding ones of the little finger.

Cases may be met with, although rarely, in which the phalanges are deficient in number, one, two, or even all being absent from the digit. Dr. William Carson, of Cincinnati, has kindly furnished me with the description of the following interesting case. The patient was a boy eight years of age, an only child, who presented a deformity consisting in the absence of the distal phalanx, and part of the second, from all the fingers of both hands, the thumbs being normal. His mother exhibited the same deformity. Her father was the parent of twenty-four children, of which number, however, but five had survived to any age, and of these three had the same malformation as their sister and her son. The grandfather was one of eleven children, in five or six of whom the defect existed. He stated that it had been observed in the family for over one hundred years.

In contrast to this hereditary transmission of the same malformation is a case reported by W. S. Montgomery Smith,[1] in which hereditary defect of the digits was observed for two generations, while a representative of the third changed the routine by possessing a supernumerary thumb. The usual deformity of the family present in several instances for two generations had been a deficiency in the toes, the big toe being present, the second absent, the third rudimentary, and the fourth and fifth webbed. The paternal grandmother, from whom the malformation could be traced, exhibited, in addition to it, absence of both thumbs and a webbed state of the fingers.

The cause of congenital deficiencies is somewhat obscure. Doubtless in the great majority of instances they originate very early in fœtal life. According to the theory of Hasse and Pauli,[2] they result from inflammatory adhesions between the amnion and the integument at a very early stage of development, the subsequent increase in the amniotic fluid causing the bands of adhesion to break up, the process bringing about distortions, amputations, etc.

Cases of intra-uterine amputation resulting from pressure of the umbilical cord would, of course, fall under the category of congenital deficiencies; but they are obviously of a different nature from instances where the member is present although imperfect in its development.

Treatment.—So great is the variety of malformations of this class that each case will, for the most part, have to be dealt with according to its own merits. To supply that which nature has failed to provide for an individual is plainly beyond the resources of surgery. On general principles, a malformed limb, unless the distortion is of an extreme degree, is of more use to its possessor than any artificial appliance could be, and therefore it is advised that the plan of treatment adopted be a conservative one. By the employment of properly-constructed apparatus a distorted hand or foot may be brought into a fairly good if not normal position, and compensation for the lack of a bone in the forearm or leg be made. To increase the muscular development of the part, massage and electricity, judiciously used, will be of service.

Operative measures may in certain cases be called for to correct the influence of a shortened muscle or a contracted fascia, or to remedy an otherwise irremediable deformity of a bone.

---

[1] Guy's Hospital Reports, 1888, vol. xlv.

[2] Archiv f. Klin. Chir., vol. xxiv.

Cases may be met with in which conservatism is out of the question, in consequence of the extreme degree of deformity of the limb, its articulations being so imperfect as to permit of little or no motion, and the member being rather an encumbrance to the individual than otherwise. Under such circumstances its removal would be advisable.

Hands deformed in consequence of the absence or defective development of fingers may sometimes be improved in appearance by surgical measures. Thus, rudimentary fingers, the phalanges of which are entirely absent or but ill developed, and which are of no service whatever, should be amputated, the scar resulting from such operation being far less unsightly than the deformity itself; and the webbed condition of some of the fingers, sometimes met with in association with defects of the hand, should be remedied by an appropriate operation. (See section on webbed fingers.)

Cases of deficiency in the toes will seldom require surgical treatment unless combined with some other deformity of the foot or leg. The unnatural appearance being concealed by the foot-wear, no interference will be called for on that score. A rudimentary or ill-developed and distorted toe, however, may be the source of annoyance, or may interfere with locomotion, and, under such circumstances, should be removed.

CONGENITAL CLUB-HAND.

This deformity is seldom seen by itself, being in most instances associated with osseous defects in the hand, wrist, or forearm.

In addition to these defects—notably imperfect development or absence of the radius, and deformities or deficiencies of the carpal, metacarpal, and phalangeal bones—its causes are similar to those which produce club-foot,—namely, pressure in utero, muscular contractions or anomalies, and paralysis.

Varieties.—Club-hand is either simple or compound. The simple varieties are named the radial, the ulnar, the palmar, and the dorsal, according to the direction of the deviation of the hand at the wrist. In the radial form the hand is in the position of abduction, in the ulnar it is adducted, in the palmar it is flexed, and in the dorsal it is extended. The most common is the palmar, in which the wrist and fingers are flexed, and the palm looks towards the flexor aspect of the forearm.

The simple forms are less frequent than the compound. Of the latter the radio-palmar is the most common. In this deformity the thumb and its metacarpal bone, some of the bones of the carpus, and part or the whole of the radius are usually absent. The hand is placed at an angle with the external border of the forearm, its radial aspect being sometimes in contact with the surface of the latter. At the inner side of the wrist the lower extremity of the ulna forms a marked projection.

The compound variety next in point of frequency is the cubito-palmar. In this form the wrist is flexed and the hand directed towards the ulnar or inner border of the forearm.

Dorsal club-hand, either simple or compound, is seldom seen.

Treatment.—Cases of an extreme degree of club-hand in conjunction with marked distortion of the extremity resulting from osseous and muscular deficiencies will seldom be improved by treatment other than the application of an apparatus with the object of partly compensating for these failures of development. Indeed, in some instances nothing whatever can be done to improve the condition, and the useless hand should be amputated. In cases of a simpler kind measures such as are employed for the correction of club-foot should be adopted: contracted tendons should be divided, an appropriate apparatus to overcome the deformity provided, and the tone of ill-developed or paralyzed muscles improved by the use of massage and electricity. After tenotomy has been performed, three or four days should be allowed to pass before the retention apparatus is applied and the process of bringing the hand towards its normal position by that means begun.

SUPERNUMERARY LIMBS.

Deformities of this kind are of extremely rare occurrence, the only cases that have been recorded, so far as I know, being the following: one of supernumerary arm, reported by Hartley,[1] the patient, a boy ten years of age, possessing an entire additional arm on the right side. A very singular case, reported by Grandin,[2] is that of a child having in the right arm two humeri, each articulating with a radius and an ulna, and between these were a third radius and ulna. There were three hands, that in what would be normally the radial side having four fingers and one thumb, the latter in a state of contraction, and on its ulnar side two rudimentary fingers. The middle hand possessed four fingers, all of them contracted, and the third hand had five fingers. Each hand was capable of independent motion.

Murray[3] has described the case of a woman with double hand, and Giraldes[4] that of a child with the same condition.

SUPERNUMERARY DIGITS—POLYDACTYLISM.

The largest group of cases of abnormalities of the extremities is that in which the deformity is due to an increase in the number of the digits or in the number of segments of which they are composed. While in the majority there is but one additional finger or toe, many cases are on record in which there have been more. Thus, Mason[5] reports an instance in which there were nine toes on the left foot. Annandale (*loc. cit.*) mentions a case in which there were seven toes on the left foot and six on the right, the individual having had also, at the time of birth, fourteen fingers; another case in which each hand had ten fingers, and each foot ten toes; and another in which there were six fingers and two thumbs on each hand.

[5] St. Thomas's Hospital Reports, 1879, vol. ix.

Polydactylism is frequently hereditary, the deformity sometimes showing itself in several successive generations of a family.

Adopting the classification of Annandale, supernumerary digits will be found to comprise four varieties:

1. A rudimentary digit attached loosely or by a pedicle to any part of the hand or foot, or to another digit.

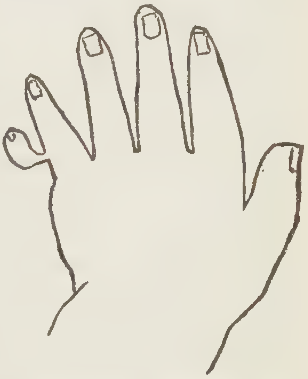
2. A more or less developed digit articulating with the head or side of a metacarpal, metatarsal, or phalangeal bone.

3. A perfect digit articulating with a metacarpal or metatarsal bone of its own.

4. A more or less developed digit united throughout its length with another digit, and articulating either with a metacarpal or metatarsal bone of its own, or with one common to it and another digit.

In regard to the first class, the digit is more or less rudimentary, having one or two ill-developed phalanges, and being attached by a slender pedicle. In the case of the hand such digits are seen most frequently on the ulnar border, sometimes growing from the hand itself, sometimes from the side of the little finger. They have been met with on the radial side, in the palm, and on the dorsal surface of the hand.

FIG. 4.



Supernumerary finger, first variety. (After Annandale.)

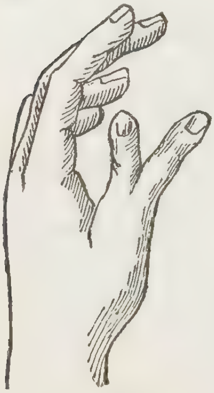
In the second kind the supernumerary digit may articulate either with an expanded or a broadened head of a metacarpal or metatarsal bone or phalanx, in conjunction with the normal digit, the two being enclosed in a common capsular ligament, or with an articular surface of its own, the head of the metacarpal, metatarsal, or phalangeal bone being in this case bifurcated so as to form two separate articular extremities, and the capsular ligament being sometimes, as in the former instance, common to both digits, and sometimes separate from that of the normal digit. When the additional digit articulates with the side of a metacarpal, metatarsal, or phalangeal bone, the articular facet for it will usually be found below the distal extremity of those bones. The articulation, as a rule, possesses a distinct and separate capsular ligament. Digits of this second variety are of little use, being generally limited in their mobility, and frequently ill developed.

In the third variety the supernumerary digit, having a metacarpal or metatarsal bone of its own, is well developed, movable, and useful, as a rule.

In the fourth class the union between the supernumerary digit and its neighbor is usually complete, and extends through their entire length.

Sometimes, however, this is not the case, the union being but partial, both in extent and in firmness. Instances of this variety are met with most frequently in the thumb and the great toe.

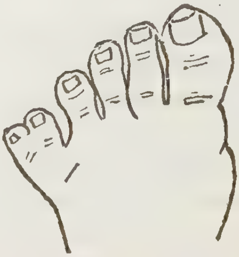
FIG. 5.



Supernumerary thumb, second variety. (After Annandale.)

It will be understood that these remarks apply to both the fingers and the toes.

FIG. 6.



Supernumerary toe, second variety. (After Annandale.)

Treatment.—Taking each variety separately, we shall be enabled to see more clearly the treatment appropriate to each. Digits of the first variety should be dealt with by removal, the operation being performed at as early an age as possible. The procedure is of the simplest kind, and consists merely in cutting through the pedicle with scissors or knife, taking care that none of it be left and that any arterial spurting which may occur be controlled by either a fine ligature or a suture.

Additional digits of the second class should also be removed; but the utmost care should be taken to preserve strict asepsis, for should there be but one capsular ligament and synovial membrane for the extra digit and the normal one, and should suppuration follow the operation, the result would be disastrous to the usefulness of the latter. When the head of the metacarpal or metatarsal bone is bifurcated, the part supporting the abnormal digit should be included in the removal. In the instances where the supernumerary digit articulates with the side of the metacarpal, metatarsal, or phalangeal bone, and the articulation is provided with its own capsule, the risk of injuring the articulation of the normal finger is not so great, but none the less the amputation should be carefully performed, with the observance of thorough asepsis. In some cases of the second variety the association of the articulation of the supernumerary digit with the normal one is so intimate that its complete removal without damage to the latter might be impossible. Under these circumstances it would be better to divide the proximal phalanx of the supernumerary digit just beyond its base, with either bone-forceps or a very fine saw, and so avoid disturbing the normal finger at all.

In the case of the toes, if in addition to a supernumerary digit of this variety there be much distortion of the normal one adjoining it, as is sometimes the case, both should be removed.

Superfluous digits of the third variety had better, as a rule, be left alone. Their removal, if attempted, would involve interference with the supernumerary metacarpal or metatarsal bones supporting them, and the resulting scar would be quite as unsightly as the normally-formed although superfluous digit, if not more so.

In cases of the fourth variety it will usually be found that the union between the supernumerary and the normal digit is so complete as to endanger the latter if removal be attempted. If the thumb be the subject of the deformity, even if the distortion be considerable, its usefulness may not be impaired to any great extent, and, although its appearance may be a source of annoyance, it does not justify our running the risk of impairing the utility of the member by an operation. In certain cases of incomplete union it may be possible to remove the supernumerary thumb with but limited injury to the normal one, care being taken, however, to preserve ample flaps from the soft parts to close in the gap left behind.

If the great toe be the seat of this deformity, and the degree of distortion be so great as to cause inconvenience or distress from pressure of the shoe, amputation of the entire toe is the only means of securing relief.

CONGENITAL UNION OF DIGITS—SYNDACTYLISM.

This deformity, like polydactylism, is one that is often met with. It consists in the union of two or more digits (1) by means of loose folds of skin,—the true "webbed" condition,—or (2) by a more complete connection of the soft parts of the fingers in addition to the skin, or (3) by fusion of the bones. The union may extend along only part of the length of the fingers, or it may be complete. Cases have been met with in which the condition was limited to the distal ends of the digits. An extreme degree of syndactylism is sometimes met with, in which all the digits of a hand or a foot are fused together and lose their identity in one ill-shaped mass or lump.

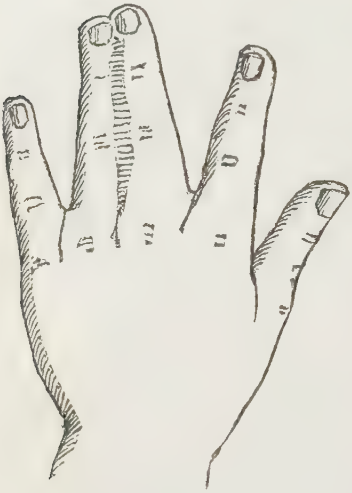
The first kind is that which is most common, and consists virtually in an exaggeration of the normal folds of skin between the fingers and toes. It is seldom that more than two digits of a hand or a foot are so united, but occasionally cases are seen where three, or even all, are "webbed." While the condition does not necessarily interfere with the motions of flexion and extension, it may limit adduction and abduction, and certainly it diminishes the freedom of individual motion of the united digits.

In the second variety the digits are held together more or less firmly, the covering of skin and fascia being common to both or all so united, and their individual movement being an impossibility. Each digit may possess its own nail, or there may be but one nail for both (or for all, in case more than two fingers be the subjects of the deformity), a longitudinal groove (or grooves) indicating the portion belonging to each. The line of separation between these digits is generally indicated by a line or depression in the integument.

Fig. 7, from the hand of a patient of mine, a twin two months old, is an example of the second variety.

In the third class fusion of all the phalanges is rare, the union existing more commonly between only the proximal phalanges, or sometimes the medial phalanges as well. Each digit has, of course, its own metacarpal or metatarsal bone. The individual movements are necessarily absent, and, although they may be separate, the distal phalanges are but slightly movable.

FIG. 7.



Webbed fingers, second variety.

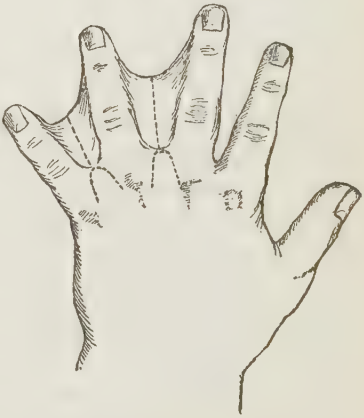
Treatment.—For obvious reasons, in the majority of the cases of this deformity which come under the surgeon's observation, the fingers are affected. United toes, free from other abnormalities, give rise to little or no inconvenience, and therefore generally require no treatment. With the fingers, of course, the case is different, and it is a matter of great importance to the individual that the united digits should be liberated, as can always be done in at least the first and second varieties. There are several methods of effecting the separation.

In cases of true "webbed fingers" (first variety), if the web be not extensive, the simple division of the folds of skin is all that is necessary. A strong disposition exists, however, for the raw surfaces to unite and thereby cause the reproduction of the web. After its division, therefore, care should be taken to keep the fingers well separated by placing between them some folds of bichloride, iodoform, or borated gauze, and keeping them there, renewing them if necessary, until the fresh surfaces have skinned over.

When the web is more extensive, one of the following operations should be chosen.

Norton's Operation.[1]—The first step consists in raising small triangular or rounded flaps on the dorsal and palmar aspects of the hand, in the clefts between the fingers, the base of the flaps being on a line with the heads of the metacarpal bones. Next the web is divided, and lastly the flaps are united by fine sutures, any tissue which prevents their easy approximation having first been divided or removed.

FIG. 8.



Norton's operation. (After Reeves.)

Didot's Operation.—An incision is made along the median line of the palmar surface of one finger, and short incisions at right angles with it are made at its extremities. A longitudinal flap, which should be as thick as possible, is then dissected up. A flap of similar shape is then raised from the dorsal aspect of the other finger, the longitudinal incision being made along its median line. Each flap is then folded around the finger to which its base is attached, and secured by sutures.

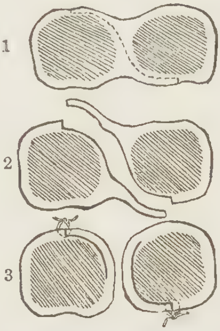
FIG. 10.



Didot's operation. Transverse section of fingers, showing the line of incision (1), the separation of the fingers (2), and the adjustment of the flaps (3). Diagrammatic. (After Noble Smith.)

In order to prevent the web, or the tissues which bind together the fingers, from reuniting, as they are especially prone to do in cases of the second variety, in which the association of the digits is quite close, it may be necessary to perform two operations. One consists in making a perforation in the base of the web and inserting a foreign body to be retained there until healing is complete, and the other in completing the cure by the division of the rest of the web. The foreign body used may be a small silver rod, having a broad, flat head at one end, and a screw upon which a nut is placed at the other. Or a rubber cord may be drawn through the perforation, and its ends, one passing up the palm, and the other up the back of the hand, secured to a wrist-band or bracelet. Of the two the last is to be preferred, for, being soft and pliable, it is not likely to give rise to much discomfort while it is worn, whereas the silver rod, being unyielding and projecting to a greater or less degree upon both the palmar and the dorsal aspect, might occasion some annoyance.

CONGENITAL CONTRACTIONS OF THE DIGITS.

Although often seen in association with other malformations of the hand or foot, congenital contractions of the fingers and toes may occasionally be met with when no other abnormal condition of the extremity is present.

The deformity is caused by either fascial or tendinous contraction, either the flexor or the extensor tendons, or both, being at fault. It is usually not prominent at birth, but becomes more noticeable as the child grows, having a distinct tendency to increase slowly. Frequently it is an hereditary peculiarity, a particular finger or toe being affected in certain members of successive generations of a family.

In all the instances that I have met with of contracted fingers, the position of the digit was that of semi-flexion, full extension being impossible, the condition depending on shortening of the flexor tendons. In the toes, while contraction in the position of flexion is more common, I have seen a few individuals in whom, owing to contraction of extensor tendons, the toe was pointed more or less upward and could not be flexed so as to rest upon the same plane as the other toes. In all these cases the great toe was the one so affected. The second toe seems to be the one most liable to contraction in the position of flexion, the degree varying in different cases. Such a deformity may give rise to discomfort, either from an ingrowing condition of the nail, which in some cases, owing to the amount of flexion, is directed vertically downward, or else from the formation of a corn, as the result of pressure of the shoe, over the prominent first interphalangeal joint.

Sometimes one or more toes will be observed to be contracted in consequence of contraction of the plantar fascia.

Treatment.—Steps should be taken to correct the deformity, especially when it is slight, at as early an age of the patient as possible. In some such cases the employment of manipulation of the contracted digit may succeed in straightening it, but, if the condition exists in consequence of contracted tendons or fascia, other means must be resorted to. When the contraction is more marked, although moderate in degree, it may perhaps be corrected by the application of a splint of wood, rubber, or metal. If this fail, operative interference will be demanded, as it always is in cases where the deformity is very marked. Under these circumstances subcutaneous division of the contracted tendons or fascia must be performed, and the digit maintained in its proper position by the use of a splint. The operation will be more successful if not performed at too early an age, for it will be found a most difficult task to keep the retaining splint in position in very young children. Cases will sometimes be met with in young persons or in adults in which a contracted toe gives rise to much distress in consequence of its overlapping the adjacent toes. In these it will be proper to see first whether tenotomy, or division of the contracted fascia, if there be any, will correct the conditions. If these measures be found useless, amputation should be advised.

CONGENITAL DISLOCATIONS.

By SAMUEL KETCH, M.D.,

AND

LE ROY W. HUBBARD, M.D.

Definition.—The definition of a congenital dislocation is implied by the term which is used to designate this class of deformities, and signifies a loss of contiguity at birth between the bones forming an articulation.

Synonymes.—German, Angeborene Verrenkung; French, Luxation congénitale.

History.—While Hippocrates and others of the ancient writers undoubtedly observed these deformities, the first scientific knowledge of them was presented by Paletta and Dupuytren in the latter part of the last century and the first part of this.

It is possible, of course, for any articulation in the body to be the seat of a congenital dislocation, and a case has been reported where every joint presented this anomaly. We have personally seen one case, to be hereafter described, in which many congenital dislocations existed; but of all the articulations the hip-joint is the one most often affected. The knee-joint has been mentioned as coming next in frequency, and isolated examples of congenital dislocation at the shoulder, the inferior maxilla, and the smaller articulations have been reported.

Among fifty-seven cases of congenital dislocations collected from the case-books of the New York Orthopædic Dispensary and Hospital, there were fifty-five cases of dislocation at the hip, one case at the knee-joint, and one at the metatarso-phalangeal articulation. Most of our knowledge, therefore, regarding this class of cases must be derived from an investigation of the conditions which present at the hip-joint, as the trouble occurs so rarely at the other articulations that little or no opportunity is afforded for their study. Consequently we shall in this article deal principally with congenital dislocations of the hip-joint.

The statistics differ somewhat in regard to the relative frequency of the bilateral and the unilateral variety of this deformity. Thus, Pravaz[1] met with four bilateral and fifteen unilateral examples; Boyer with thirteen bilateral and twelve unilateral; of twenty-six cases which Dupuytren saw, only two or three were single, and of twenty cases reported by Holmes, sixteen were double. Stedman[1] analyzed twenty-five consecutive cases, and found fifteen unilateral and ten bilateral examples.

---

[1] Traité théorique et pratique des Luxations congénitales du Fémur.

Of the fifty-five cases of congenital dislocation of the hip-joint, representing the total number applying for relief at the New York Orthopædic Dispensary during a period of ten years, from 1878 to 1888 inclusive, both joints were affected in twenty instances and one joint alone in thirty-five instances.

All of these cases have been personally examined by the authors, and they have been analyzed with special reference to etiology, sex, and location, with the following results. Of the total number, twelve occurred in males and forty-three in females. Of the thirty-five cases in which only one joint was affected, in eleven it was the right and in twenty-four the left. Three of the eleven cases with right-side deformity were males and eight females, and of the twenty-four cases whose left hip was affected four were males and twenty females. The twenty bilateral cases included five males and fifteen females. A comparison of the total number and each separate class will show that the proportion of females to males afflicted with this deformity was in the ratio of about three and one-half to one. Of Dupuytren's twenty-six cases twenty-two were females and four males, and of Holmes's twenty cases seven were males. There have been attempts to explain this preponderance of female cases, but none of them have been satisfactory, though the disproportion has been noticed by all observers. The left hip seems to be the favorite seat of the affection in the proportion of five to one. The proportion of bilateral to unilateral cases was greater than that observed by some writers and smaller than that observed by others,—viz., $36\frac{20}{55}$ per cent.

Etiology.—The etiology of all congenital deformities is obscure, and that of congenital dislocations is no exception to the rule. The theories advanced have been almost as numerous as the authors of articles on the subject, but none of them has trustworthy proofs behind it, and few are even plausible.

It may be interesting briefly to mention a few of the causes advanced.

1. Heredity (Dupuytren, and afterwards Stromeyer and Schreger).

2. External violence acting upon the fœtus in utero (J. L. Petit).

3. Primitive alteration in the germ, or an aberration of the primitive force (Dupuytren).

4. Arrest of the development of the osseous portion forming the cotyloid cavity (Breschet).

5. Articular maladies occurring in the fœtus during intra-uterine life (M. Parise and others).

---

[1] Buck's Hand-Book of the Medical Sciences.

6. Primitive alteration in the nervous centres (Chaussier, revived by Delpech and Guérin).

7. "Pathological spasmodic contractions of the muscular tissue, resulting from a perverted or disturbed condition of the excito-motor apparatus of the medulla spinalis" (Carnochan).

A careful examination of the histories of the cases reported above was made with reference to the cause of the deformity as stated by the mothers of the patients, and produced the following results. In forty-six cases no cause whatever could be assigned. Two were ascribed to a fall of the child in infancy, one to a fall of the mother before the birth of the child, one to a supposed accident to the mother, but of which she was very uncertain, one to an early attack of erysipelas, one to an abscess at the left external malleolus in a case of double dislocation, one to convulsions at fifteen months, one to measles, and one was a premature delivery.

Brodhurst[1] states that this deformity never occurs except in preternatural labors, and usually in breech presentations. But a careful inquiry in these cases showed that most of the labors were perfectly normal.

Dupuytren based his idea of heredity upon one remarkable case, but subsequent investigations have not strengthened the argument. In the cases analyzed by us no well-marked history of the deformity appearing often in the family was observed.

Moreover, all the causes assigned, with possibly one exception, could have no connection with the deformity in question, as they occurred either at a time when the joint was fully formed or after the birth of the child. The exception which might be noted is the case of the woman who fell early in pregnancy; but cases occurring during confinement from forcible delivery, etc., ought to be included, strictly speaking, under traumatic dislocations. Hueter has shown that where sufficient violence occurs to dislocate the femur a diastasis or separation of the epiphysis is more likely to result.

The theory of intra-uterine joint-inflammations seems to be scarcely tenable, as the results of such ante-partum diseases are never present when the joints are examined after birth.

If the deformity were due to marked changes in the spinal cord, either as the result of deficiency in nerve-tissue or in consequence of inflammatory action producing paralysis of certain groups of muscles, we should suppose that the effects of such paralysis would be apparent after birth. While it is true, as Guérin[2] states, that in some cases there is atrophy of the thigh-muscles, we have never observed anything like a true paralysis.

The theory of Carnochan[3] seems to be a very fanciful one and incapable of demonstration, for it is difficult to imagine spasmodic contraction of muscles sufficient to produce luxation of the femora which would disappear as soon as the child was born.

---

[1] Lectures on Orthopædic Surgery.

[2] Recherches sur les Luxations congénitales.

[3] Etiology, Pathology, and Treatment of Congenital Dislocations of the Head of the Femur.

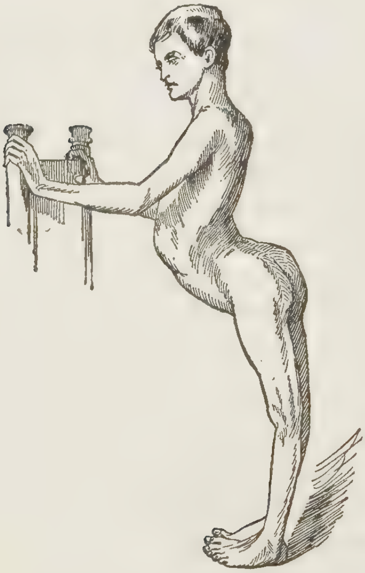
The idea that congenital dislocations are the result of developmental anomalies is the most rational of all, and receives support from the fact that children who are the subjects of the deformity are generally healthy at birth, showing entire absence of disease, past or present, of the joint-structures involved. Again, the occurrence of cases of multiple congenital dislocations would tend to support the theory of improper development or vice of conformation.

The following case will perhaps serve as an illustration. For the photographs (Figs. 1 and 2) and very careful notes upon the case we are indebted to Dr. T. Halsted Myers, of New York City.

Francis M., a patient in the service of Dr. Ketch at Randall's Island Hospital, was first seen in the spring of 1887. For some time the attendants and physicians at the hospital had noticed the peculiar walk of the child, but it had been ascribed to the condition of the feet, as they were in the position of a marked talipes equinus. It was impossible to obtain any early history of the patient. The following are Dr. Myers's notes on the case.

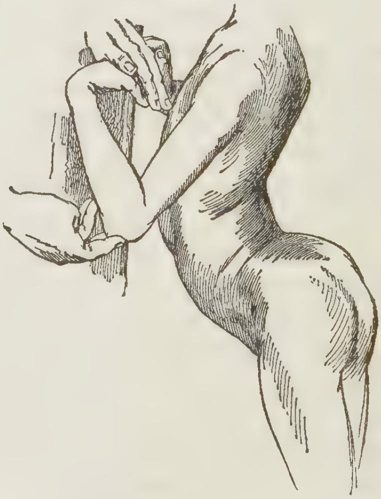
Francis M. Bilateral congenital dislocation of the femora; bilateral dislocation of the head of the radii; abnormal laxity of all the joint-ligaments; double congenital talipes equino-varus.

FIG. 1.



Shows the talipes, the hyperextension at the knee, the prominence of the trochanters, the consequent spinal lordosis, also the prominence over the head of the radius.

FIG. 2.



Shows the prominent trochanters, the lordosis, the dislocation of the radial head, and the hyperextension at the wrist and metacarpo-phalangeal joints.

In this case the typical pose and walk are exaggerated by the condition of talipes. To maintain a position of stable equilibrium there must be, and is here, a hyperextension at the knee to allow the heels to touch the ground, and this in turn requires a compensatory exaggeration of lordosis.

Examination of the individual joints shows that the inter-phalangeal joints of the toes allow an extreme lateral and antero-posterior gliding motion without actual dislocation, flexion to ninety degrees and extension to one hundred and ten degrees.

The metatarso-phalangeal joints present the same degree of laxity of their ligaments. Flexion is possible to eighty degrees; extension to one hundred and ten degrees.

The tarsal and ankle-joint motions are restricted, owing to the equino-varus deformity. The inner band of the plantar fascia is tense and prominent, and the tendons of the posterior tibial group of muscles prevent full flexion at the ankle.

At the knee-joint flexion is allowed till the leg touches the thigh; extension is possible to one hundred and thirty-five degrees. There is also a marked lateral mobility at this joint. Slight rotation also is allowed in the extended position, while in flexion of forty-five, ninety, or one hundred and thirty-five degrees as much as forty-five degrees of rotation is possible. The patella can be inclined on either its inner or its outer edge at an angle of fifty degrees.

At the hip-joint the characteristic deformity is present, the head of the femur being readily felt on the dorsum ilii. There is very little telescoping of the joint, but rotation is possible through ninety degrees inward as well as outward. The trochanter major lies half an inch above the level of the anterior superior iliac spine, even when the child is lying down. Extension, abduction, and adduction are normal. Flexion can be made to forty degrees.

The spine is flexible, but not markedly so.

In the upper extremity the inter-phalangeal joints allow the same free lateral and antero-posterior gliding motion as was observed between the toes. Flexion and extension to ninety degrees are possible. The metacarpo-phalangeal joints allow extension to one hundred degrees.

At the wrist there are flexion and extension to seventy degrees, and at the inferior radio-ulnar articulation motion is very free, allowing complete dislocation of the bones in an antero-posterior direction.

At the elbow-joint pronation and supination are not restricted; there is also free flexion except in extreme supination; extension is exaggerated twenty degrees. The head of the radius is completely dislocated upward and forward, lying directly in front of the external condyle of the humerus in the radial depression; and the dislocation cannot be reduced. The prominence at the outer aspect of the joint usually produced by the external condyle is here formed by the head of the radius. (See Fig. 2.)

At the shoulder-joint no abnormalities were discovered. The lax ligaments of the sterno-clavicular articulation allow almost a complete dislocation upward and backward.

Both sides of the body are similarly affected, but the left side to a more marked degree.

To summarize, then, we may say that the cause of congenital dislocations is probably some change in the central nervous system of the fœtus, which produces a perverted development and growth of the osseous, the ligamentous, or the muscular tissues of the joint, or perhaps of all of them together.

Pathology.—The appearance of joints which have been the seat of congenital dislocation varies somewhat with the age of the patient, and there is consequently some difference in the descriptions made by the several observers. In the essential points, however, all agree.

The acetabulum is sometimes deficient, but more commonly exists as an oval or triangular shallow depression in the bone: in rare instances it may present as a bony protuberance. Sometimes there is an abortive attempt to form a new acetabulum on the dorsum ilii, without, however, any true bony deposit, and the depression so formed may be lined with a synovial membrane and have a fibrous capsule attached to its margin, or it may be smooth and hard. The old capsule usually remains attached to the margin of the rudimentary acetabulum if one exists, and may be simply stretched and loosened, allowing the head of the femur to play up and down within itself, or may be perforated so as to allow the head of the bone to escape entirely. Sometimes it is found converted into a ligamentous cord, and in such cases there is no attempt to form a new acetabulum. Carnochan (*loc. cit.*) found, in the case of a subject seventy years of age, that a new capsule had been formed of fibrous tissue, which was attached to the annular rent in the old capsule. The head of the femur is sometimes merely changed in form, being smaller than normal and flattened, or it may be entirely absent. In Carnochan's case it was friable, and the articular cartilage was very thin and delicate. The muscles about the joint present some changes, part of them being contracted and perhaps showing evidence of fatty degeneration, while others are hypertrophied.

In congenital dislocation of the knee-joint the tibia is generally drawn backward, presenting in the popliteal space, but several cases of forward dislocation have been reported. When the dislocation is backward, the ligamentum patellæ is stretched and the hamstring tendons are contracted; when forward, the reverse is true. The crucial ligaments are relaxed in both cases. The patella is sometimes absent, but generally is present, though out of its usual position.

Luxations of the other joints have been so rare that their pathology has not been studied.

Symptoms.—The symptoms of a congenital dislocation at the hip vary materially, depending on whether the affection is unilateral or bilateral.

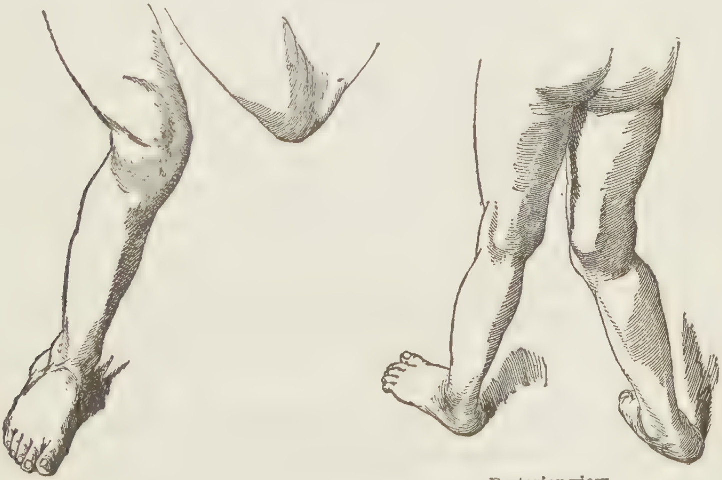
In either case the deformity is not discovered until the child begins to walk, and it is doubtful if a diagnosis could be made before that time, as, in all probability, the head of the femur does not leave the acetabulum until the weight of the body is brought upon it. In case the deformity is bilateral, the gait of the child is a peculiar rolling or wabbling one, which is characteristic, and is the result of an endeavor to balance the side of the pelvis upon the sliding head of the femur. The heels are not usually brought to the ground, the weight being borne upon the balls of the feet. This peculiar method of locomotion is most marked when the child walks slowly, since in rapid walking or in running the weight of the body is transferred so quickly from one side to the other that the femora slide up only a short distance upon the ilii.

If the patient is stripped, two things will be prominently noticed,—viz., the extreme breadth of the pelvis and a lordosis of the lumbar spine. There is also obliteration of the normal joint-outlines, the nates being flattened below, while at the level of the iliac crests the hips are flaring. The thighs are separated from each other above, giving the perineum a square appearance. The lordosis of the spine is produced by an effort to sustain an equilibrium, since the heads of the femora are placed posterior to the normal acetabula.

If the child is placed upon a flat surface on its back and the thigh is flexed to a right angle with the pelvis, which is at the same time held firmly in position with one hand, and with the other grasping the thigh upward traction is made, generally the head of the bone can be felt to move up and down upon the ilium. The range of motion varies from half an inch to two inches, and frequently the head of the femur can be felt passing over a depression or slight projection, accompanied by a distinct click. If the case has existed long enough to have formed a new socket and new attachments, of course this sign will be wanting or greatly modified. An application of Nélaton's line test will show the great trochanter to be distinctly raised, often as much as two inches.

In unilateral dislocation the walk is characterized by a distinct limp, varying in degree according to the amount of shortening and the age of the patient. Inspection will show only one joint affected as described above. The lordosis of the spine is less marked, and there is generally some lateral deviation, with the convexity towards the affected side. Examination on the table shows an inequality in the length of the limbs, but by using traction and making counterpressure upon the perineum this inequality can frequently be greatly lessened, and sometimes obliterated. There is the same telescoping of the joint as in the bilateral variety, and the trochanter on the affected side lies above Nélaton's line. Motion of the joint in both cases is usually nearly or quite perfect in all directions, except a slight restriction to adduction and outward rotation.

FIG. 3.



Anterior view. Posterior view.

Congenital dislocation of the tibia forward and outward. (From a photograph of a patient at the New York Orthopædic Dispensary.)

Dislocation at the knee is generally discovered quite early, as the deformity is well marked and the joint is more exposed than the hip. In case of dislocation of the tibia forward, the limb is in a partly-flexed position and complete motion in either direction is impossible, while the condyles of the femur are prominent in the popliteal space. In the backward dislocation, extension is impossible, the condyles can be felt anterior to the joint, and the head of the tibia in the popliteal space. The illustrations on the preceding page are from a photograph of a patient at the New York Orthopædic Dispensary. She was eighteen months old when she came, and the parents had noticed ever since she began to walk that the right knee "gave way" when she stepped upon it. There was no hereditary history of similar deformities. Examination showed relaxed ligaments at the joint, especially the internal, and a dislocation forward and outward of the tibia, with rotation outward, making the internal condyle of the femur prominent.

The condition resembles a marked genu valgum, as is easily seen by the illustrations.

Diagnosis.—It seems scarcely possible that a case of bilateral congenital dislocation could be mistaken for anything else; but Hilton[1] reports two cases seen by him in which apparatus for spinal disease had been worn, and we have recently seen a child at the New York Orthopædic Dispensary who wore for several weeks a plaster jacket which had been applied under the impression that the case was one of lumbar Pott's disease. The mistake doubtless arises from the lordosis of the spine which is present in these cases, as this is frequently a symptom of lumbar spondylitis. But an examination will show no deformity or rigidity of the spine nor any limitation of the thighs to extension, all of which are prominent symptoms in Pott's disease involving this region. The mistake is rather a serious one, for the application of any apparatus to overcome the lordosis of course destroys the compensating position, and the patient walks more unsteadily than before.

A mistake might be more easily made in the case of a unilateral deformity.

The unilateral congenital dislocation can be distinguished from the traumatic variety by remembering that the latter is very rare in children, that there is generally a history of injury, and that the child once walked all right, while in the congenital form the limp has been noticed from the time the child began to walk.

Separation of the epiphysis is sometimes met with in children; but here there is pain on motion, and usually distinct crepitus, which differs from the tendinous click sometimes found in moving a joint which is congenitally dislocated.

A congenital dislocation is distinguished from hip-disease by the absence of pain and reflex muscular spasm and by the freedom of motion in all directions.

Congenital shortening of the limb or the shortening which accompanies an infantile paralysis might be mistaken for a congenital dislocation, but a careful examination of the joint will at once establish the diagnosis, since in congenital shortening or that accompanying infantile paralysis the femur is held firmly in its normal position and the trochanter is not raised.

---

[1] Rest and Pain.

The distinction between a traumatic and a congenital dislocation at the knee is readily determined by the history.

The case illustrated resembles very much an exaggerated form of genu valgum; but manipulation of the joint disclosed the luxation of the bones and made the diagnosis easy. If every case is examined carefully and thoroughly, it is scarcely possible to make a mistake; but a careless, superficial examination may easily lead to error.

Prognosis.—The deformity under consideration, of course, has no influence upon the general health of the individual suffering from it, and there is no reason why such children should not live as long as those whose hips are normal. But the prognosis, regarding the cure of the deformity, is unfavorable, and the shortening usually increases. Cures have been reported, but treatment must be begun very early and kept up unceasingly for months, or even years, while the result is still uncertain. The plan demands not only employment of proper means on the part of the surgeon, but also such co-operation on the part of the patient and parents that it can seldom be carried out. Cases of self-cure do occur, as we have seen ourselves,—*i.e.*, the heads of the femora become fixed in a new position, and the gait is improved,—but the shortened extremities and the lordosed spine remain.

Treatment.—If the treatment of this affection is attempted, it must be begun, as stated above, very early, and must be unremittent and long continued. The general plan which has been adopted by all surgeons, outside of operative measures, consists in the gradual drawing down of the head of the bone by traction until it reaches the acetabulum on its proper site, and keeping it there until it will remain without the use of retentive force. When the dislocation is bilateral, the child must be kept upon its back fixed in one position while traction is made upon the thighs. Pravaz, of Lyons, has employed this procedure, and reports several perfect cures. The cure reported by Buckminster Brown[1] was certainly a very satisfactory one, and illustrates what can be done in these cases by perseverance on the part of both surgeon and parents.

If this plan of treatment is adopted, the child must be placed upon a smooth and moderately hard bed, and the trunk so secured that it cannot move up or down or from side to side without assistance. The thighs are flexed upon the trunk at an angle of about one hundred and fifty degrees, and traction is made in this direction. The force employed must be graduated according to the resistance, and may be increased as the patient becomes accustomed to it. After the head of the bone is brought down, it must be kept in this position for such a period that when the traction force is relaxed there will be no tendency to a return of the deformity. Then is the time to begin passive motion. This must be done in a most careful manner, for the application of undue violence might destroy in a moment the work of months.

---

[1] Boston Medical and Surgical Journal, June 4, 1885.

During the period of traction and following it, pressure should be made upon the trochanters by means of an elastic belt passing around the hips, and prevented from slipping up by means of padded straps passing under the perineum. After the bones show no tendency to displacement, an apparatus similar to that employed for double hip-joint disease may be applied, and the child may be allowed to move about in a wheel-crutch. After six months or a year the extension-apparatus may be removed, and the patient, still wearing the trochanteric support, may be permitted to use a wheel or other crutch, and gradually begin to bear some weight upon the limbs.

The unilateral variety has been treated, in some cases with marked success, by means of the Davis hip-splint or a modification of it in connection with pressure over the trochanter. Dr. John Ridlow has reported a case[1] treated in this manner in which he obtained a very excellent result, reducing a shortening of two and one-half inches to half an inch in about one year and a half. If this cannot be tried, the lameness may be greatly modified by means of the trochanteric belt and a high shoe. If there is atrophy of any of the muscles, of course massage, douches, and electricity are indicated.

Several attempts have been made within the last few years to cure this condition by an operation, but the results have not been sufficiently satisfactory to lead to a general adoption of any of the plans proposed.

In 1874, E. Rose performed resection of the articular extremity of the femur, and the same operation has been done by Margary.[2] The latter opens the joint freely by a straight incision from the trochanter to the posterior superior spine, the thigh being adducted and flexed to an angle of forty-five degrees. The head is severed by means of an Adams saw. A drainage-tube is inserted and the wound is dressed antiseptically. Extension of about seven pounds' pull is made immediately. He reports two cases, in which the results were excellent. The deformity was markedly less, the trochanters were not prominent, the lordosis of the spine had disappeared, and both patients walked with hardly a perceptible limp.

In 1882, Margary performed another operation, which on theoretical grounds seems preferable to exsection. He opened the joint by means of a T-shaped incision, and chiselled out the acetabulum sufficiently to receive something over half of the head of the femur. The dislocation was reduced, and the capsule strengthened by a strip of periosteum. Unfortunately, the boy died of pyæmia on the eleventh day, probably caused by septic catgut. We have not seen a report of any subsequent operation.

A congenital dislocation of the knee-joint is treated by reducing the deformity, which is generally easily accomplished, and then applying a splint which will retain the displaced bone in its new position. The results in these cases are quite satisfactory.

CLUB-FOOT.

By E. H. BRADFORD, M.D.,

AND

E. G. BRACKETT, M.D.

Synonymes.—Reel-foot, Stump-foot, Talipes, Pes contortus, Kyllosis; French, Pied bot; German, Klumpfuss.

Definition.—Club-foot, or talipes, is an abnormal position of the foot in its relation to the leg. The name is popularly applied to that deformity in which the foot is twisted inward, so that the weight is borne on the outer side and front, instead of on the sole.

Etiology.—The deformity is usually congenital, but it may also be acquired after impairment of muscular strength, as occurs in infantile paralysis. As to its frequency authorities vary. Tamplin, out of ten thousand two hundred and seventeen cases of deformity, met with one thousand seven hundred and eighty club-feet. Of this number six thousand seven hundred and fifty-four were congenital. Duval found in one thousand cases five hundred and seventy-four congenital. Choussier, out of twenty-two thousand nine hundred and twenty-three newly-born infants, reports thirty-seven cases of club-foot, and Lannelongue, in fifteen thousand two hundred and twenty-nine births at the Maternity Hospital, found eight.

CONGENITAL TALIPES.

Causation.—Heredity, on the part of both the father and the mother, has been established without doubt in a certain number of cases, but in a very large majority no trace of similar deformity in ancestors can be found. Devay and Boudin report that more cases are found in children from marriages of kin than among others,—one in one hundred and sixty-four births from marriages of kin, to one in nineteen hundred and three births from other marriages.

There are three chief theories which are advocated to explain the deformity in uterine life: (1) abnormal compression in the uterine cavity,—the mechanical theory; (2) retraction or paralysis of muscles, depending on lesion of the nervous system; (3) arrest of proper development of the foot.

The first of these theories is as old as Hippocrates. Ambrose Paré and

Cruveilhier maintained the same idea, with the addition of a suppressed blow received by the mother. Cruveilhier states that when club-foot is single it always affects the foot which lies anteriorly, and that when double this foot is affected to a greater degree. Malgaigne held the same opinion. The claim that this is caused by deficiency of liquor amnii is not substantiated by fact, and much is urged against the theory on this ground, as an absence of amniotic fluid is not found, as a rule, in cases of birth of infants with club-foot, the reverse being asserted by Duval, while scantiness of amniotic fluid has not been noticed as giving rise to the deformity. Furthermore, the deformity is noticed before the fourth or fifth month of intra-uterine life, at a time when the amniotic fluid is abundant and when no intra-uterine pressure is possible.

The theory of pressure is based on mechanical principles, and involves the disturbance of those changes in position of the fœtus which seem to be essential to its perfect development. Of this view there are many supporters, among whom are Berg, Volkmann, Cocher, Vogt, Banga, Parker, and others. It was brought into prominence in 1884 by Berg, who claimed that in an early stage of fœtal development the feet are placed in a position of equino-varus, and that later, by a rotation inward or torsion of the lower extremities, the soles of the feet are brought in contact with the uterine wall and this abnormal position is corrected. The maintenance of this deformity after birth is due to a change in the structure of the foot from the normal, this difference being both in ligaments and in bones.

Against this theory of mechanical pressure it may be objected that prominently flexed knees, which should show distortion, are very rare. The normal rotation of the foot is due, not to the muscular power, as it occurs at a time when there are no muscles, but to the growth of the parts. At an early stage of uterine life these are rotated outward, so that when the surface of the thigh and the tibial border of the leg are pressed against the abdomen, the legs crossing each other at their middle and the limbs being bound at the knees, uterine pressure with the limb in this position necessarily confirms the position of equino-varus. But the lower extremities alter their position: the thighs are drawn inward and rotated so that the anterior surface instead of the inner surface lies next to the abdomen, and the soles instead of the outer surface of the foot are pressing against the uterine wall.

The second theory has the support of many writers. The theory has been held of alteration of the muscles with or without lesions of the central nervous system. Morgagni, Benjamin Bell, and Delpech believed that a contraction of certain muscles occasioned the deformity. Béclard believed that the cause lay in the weakness of other muscles. In both of these theories the chief rule holds. In the nervous system they are results of central or peripheral disturbance, and in confirmation of this view may be cited the fact that the deformity is often seen in hydrocephalic and anencephalic fœtuses, and in those suffering from spina bifida. On the other hand, however, in a large majority of cases no alteration of the nervous system can be found. Out of six hundred and eighty-eight cases of congenital varus in the London hospitals, only two were affected with spina bifida. Duval, out of five hundred and seventy-four cases, found no case with other deformity. Lannelongue in seventy-eight cases of monstrosities found twenty-seven free from club-foot, and in thirty-two cases of spina bifida and encephalocele found only four with club-foot.

In favor of this, examples of analogy are quoted,—as, that deformity from nervous diseases often attains a higher degree on the right than on the left side, and that this is true with congenital club-foot, that from cerebro-spinal affections talipes varus is more common than talipes valgus, and that distortion is more common in the lower extremities.

The third theory, that of arrest of development of the foot, is the one maintained by Meckel, St.-Hilaire, Adams, Hueter, and others. According to these authors, as the feet are developed, at the sixth or seventh week, the fœtus normally has the sole turned inward, and a permanance of this position would give a club-foot. Cruveilhier has denied this anatomical fact, but it is maintained by Martin and others.

Although this theory explains the deformity of varus, it is incapable of explaining the other forms of congenital talipes. But it has been modified so as to admit not only the arrest of development, properly so called, but also the malformation of the bone which forms the skeleton, an opinion defended by Bouvier, Brocher, Lannelongue, and others.

In short, it may be said that we are entirely ignorant of the causation of club-foot, and unable to give a satisfactory explanation of it.

An acquired deformity, which is not paralytic, may result from several causes, mostly mechanical, such as long-continued faulty position of the foot in bed, the weight of the bedclothes falling upon the toes causing the foot to drop down and turn in. This, however, is rarely of sufficient severity to simulate true club-foot. Inversion of the foot may also follow inflammation of the tarsus, but this is seldom severe. These acquired deformities are often the result either of chronic inflammation of the joint, as in rheumatism or gout, or of the weight of the body in standing, the latter causing flat-foot or valgus. Any interference with the muscular equilibrium may give rise to deformity and to faulty attitudes of the foot. When the foot is abandoned without support to its own weight, it is drawn in the direction of the strongest muscles, and an equinus results, as is often seen in fracture of a leg or after inflammation of the tibio-tarsals.

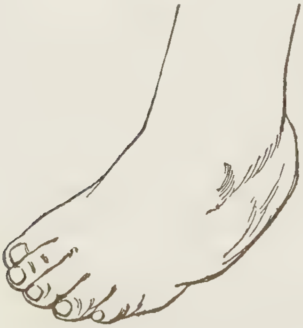
True club-foot is rarely produced by spasm of the muscles, although distortion is often brought about by certain nervous conditions attended with spasm. The deformity is usually nothing more than an exaggeration of a normal motion, most frequently being an equinus from contraction of the soleus and gastrocnemius, in spastic hemiplegia and paraplegia. The usual form occurs after paralysis, when certain muscles or groups of muscles are left either entirely paralyzed or weakened. A partial is always more to be dreaded than a total paralysis. The foot in the act of walking, instead of striking the ground as it normally should, is not sustained in its proper position, and thus the weight of the body still further twists it and develops the tendency to deformity. Volkmann has shown that positions which are assumed as the result of gravity become permanent, and that the shortening is due, not to contraction of the muscles, but to the growth of the limb.

Anatomy.—In congenital talipes there are essential structural changes involving both ligaments and bones. In bone this change consists mainly in a deviation from the normal of the axes of the articular surfaces, this being associated of necessity with actual change in the shape of the bones. The changes in the ligaments are such as result from the former condition, they being shortened over the concave surfaces and lengthened over the convex, and therefore so arranged as to hold the bones firmly in the unnatural position which is assumed, thus preventing the return of the foot to a normal condition. The greatest variation in structure from the normal occurs in equino-varus. Each will require individual consideration.

Varus.—This variety is almost universally associated with equinus, making the equino-varus, so that in description this form alone will be regarded.

Equino-Varus.—The great majority of cases of club-feet are of this form. All degrees are seen, from a slight twist to a condition in which the soles are in apposition with the inner surface of the leg. In this deformity the foot is flexed and inverted and the toes are turned inward. Pressure is borne either on the outer border of the foot, or, if the inversion be greater, on the dorsum. The position of the foot is such that the weight of the body tends to increase the deformity rather than to correct it, and in uncorrected cases bursæ and callosities form over the anterior part of the dorsum, which frequently become inflamed and limit the person's activity.

FIG. 1.



Dorsal surface of club-foot.

The distortion is of two kinds,—a movement of extension which takes place at the ankle-joint, and a movement of inversion which takes place at the transverse tarsal joint. The heel is so elevated that the sole and the toes are turned to the inside instead of downward, and the flexion of the inner border is such that the internal border presents a concavity and the external a convexity.

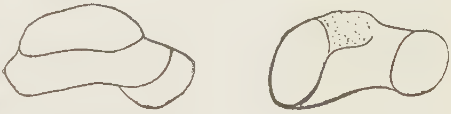
Extension of the foot is prevented by the tendo Achillis, and eversion by the tibialis posticus, deep flexors, fasciæ, and ligaments of the sole and the inner side of the foot. In this deformity the dissection will show anatomical changes varying according to the age of the distortion.

The os calcis by the elevation of the tuberosity is drawn from a horizontal into a more or less vertical position. It is also rotated on its vertical axis, so that its anterior extremity is directed inward, and the posterior outward towards the fibula. Its posterior tuberosity is less developed than normal.

The cuboid bone maintains its connection with the os calcis, and follows the inward direction of the anterior extremity of the bone.

The astragalus does not partake of this rotation on the vertical axis, but follows the os calcis in its rotation forward on its horizontal axis, so that only the posterior portion of its superior articular surface is in contact with the articular surface of the tibia, and the anterior part of its anterior facet projects beneath the skin of the dorsum of the foot. Besides this displacement, the structural changes occurring in the astragalus are of great interest, being more pronounced, and playing so important a part in the maintenance of the deformity and forming an obstacle to its correction. This change consists in an alteration of the angle which the neck makes with the body, this being so increased that the neck and articular facet point to a greater degree inward. The normal angle is thirty-eight degrees (average), as given by Parker, and in the adult healthy foot the average is twenty-six and one-sixth degrees. In five cases of equino-varus the average was forty-nine and one-half degrees, varying between sixty-four and thirty-one. This deviation from the normal structure is shown in Fig. 2.

Fig. 2.



Normal astragalus. Astragalus from a club-foot.

(From Adams.)

The formation which ordinarily exists in this deformity is considered by Parker and Shattuck as the normal one in monkeys; yet these animals are not talipedic, and this formation is not constant in them, if it exists at all. In two specimens examined the angle of inclination was not over twenty degrees. In two it was thirty degrees and thirty-five degrees, but in these the perpendicular of the plane of the articular surface was not a continuation of the line of the neck, but was nearly directly forward.

This condition also has the effect of approximating the scaphoid and the inner malleolus, so that in some cases on the inner side of the malleolus there is formed a facet. The cuneiform bones, with the scaphoid, are drawn inward and upward towards the internal malleolus. The three cuneiform and the three metarsal bones, being closely connected with the scaphoid, are more twisted than the cuboid, though the metatarsals are not equally drawn in the rotation from without inward, but are spread out somewhat like the branches of a fan, in such a way that the anterior part of the foot is enlarged more than normal. In the medio-tarsal articulation a species of subluxation occurs by which the head of the astragalus is partly uncovered, the scaphoid being brought to the inner side towards the internal malleolus, sometimes touching it, so that in some instances a bursa is formed between them.

In addition to the changes in the foot there is frequently a slight alteration in the shape of the femur.

The alterations in the ligaments vary with the degree of deformity, but in all except the slighter cases form a serious obstacle to the cure. The internal lateral and posterior and plantar ligaments are chiefly involved. The anterior portion of the internal lateral, which passes from the malleolus to the scaphoid, frequently offers great resistance in the attempt to correct the position. Parker and Shattuck found on dissection that the deformity persisted after the muscles were dissected off, and not till certain of the ligaments had been divided was reduction possible. Parker considers the ligaments as holding the chief place in the maintenance of this deformity, and as being the only constant anatomical hinderance to rectification.

The different tendons assume an abnormal direction, and in general are carried farther to the inside, this being especially true of the tibialis anticus, the common extensor of the toes, and the long extensor of the great toe. The extreme extension of the phalanges on the metatarsal bones makes the extensor tendons of the toes very prominent, and this may cause painful pressure, which makes walking so painful as to necessitate their section.

As a rule, the muscles do not present at birth any alteration in structure. This is true of the nerves also.

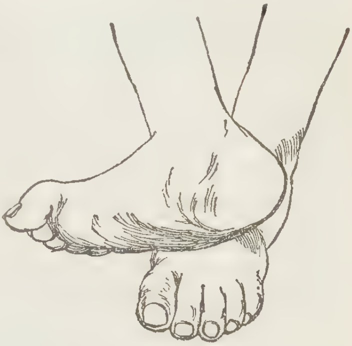
Valgus.—Congenital valgus is much more rare than varus. It consists of a turning out of the foot, and usually the heel is drawn up. In standing the external border of the foot leaves the ground, and the whole weight of the body falls on the internal side of the os calcis, the inner malleolus, and the tubercle of the scaphoid. Walking is much more uncertain than in varus, and the nerves and vessels are liable to be compressed, causing painful locomotion.

The shape of the bones is but little altered, but their relative positions undergo more or less change. The axis of the os calcis is turned obliquely from behind forward and from within outward, and an articulation is formed between the os calcis and the external malleolus. The tuberosity is raised, and the bone tilted forward. The cuboid and scaphoid are rotated outward, and their outer border raised so that one part of the articular surface is left uncovered by the scaphoid.

Equinus.—Equinus is the rarest of congenital deformities and the most common among the acquired. All degrees occur. It may be so severe that the dorsum of the foot is simply a continuation of the line of the leg, or the heel may be only slightly lifted from the ground. In some cases the deformity is due less to the raising of the calcaneus than to a depression of the head of the astragalus. The axis of the astragalus may form an obtuse or even a right angle with that of the os calcis, so that the facet of the astragalus on the latter may be obliquely forward, and the astragalus depressed almost in a vertical line. A strong flexion of the medio-tarsal joint may take place, increasing the arch of the foot.

Calcaneus.—In this deformity the anterior part of the foot is raised, and locomotion takes place on the heel. The degree of distortion varies from a right angle with the leg to a complete parallelism of the axis of the foot with that of the leg. There is usually a certain amount of abduction of the foot, which is due to a greater prominence of the action of the external extensors of the toes and the peroneus brevis. A calcaneo-valgus is thus produced, and in place of the normal arch this part of the foot presents a marked convexity. (Fig. 3.)

FIG. 3.



In many of the older cases there is no contraction which prevents the foot from being brought to a right angle with the leg, but the extensors are so weakened that there is little control over the anterior part of the foot. The articular displacement is exactly the reverse of what is found in equinus. The os calcis is deformed and enlarged, and in extreme cases its axis may be vertical, the weight of the body falling entirely on the end.

Flat-Foot.—In this condition the normal arch of the foot is obliterated, the inner border approaching the ground in proportion to the amount of deformity, so that in some cases the entire sole rests upon the ground. There are two forms, the congenital, which is analogous to valgus, and the acquired. The congenital form may be observed in certain infants, especially negroes, and is compatible with a useful member. In addition to this is the rachitic flat-foot, sometimes appearing before the child begins to stand.

Ordinarily there is no structural change in congenital flat-foot, but certain conditions have occasionally been observed, which, however, must be regarded as anomalous. Hall reports two cases of dorsal union: 1st, of the scaphoid with the os calcis; 2d, of the scaphoid with the cuneiform, resulting from an inflammatory process. In the former the foot was held in the position of a severe degree of flat-foot; in the latter, in that of a light grade of the deformity. Four specimens in the Vienna Anatomical Institute show congenital union of the os calcis with the scaphoid, with a marked valgus.[1]

Acquired Flat-Foot.—According to Duchenne, this form is always painful and causes notable interference with the usefulness of the limb. Hayward found sixty-five per cent. of cases of flat-foot between the ages of fifteen and twenty. As a predisposing influence of this deformity, the rapid growth, which may be accompanied by general muscular weakness, is important.

This condition is the result of the giving way of some portion of the structures which form the arch. The astragalus is usually considered the key-stone of this arch, but this is denied by Collin, and with good reason. The posterior pillar is formed by the os calcis, and the anterior by the scaphoid, cuneiform, and three inner metatarsal bones. The extremities of the two pillars are anchored by the ligaments, and strengthened by the tendons of the tibialis posticus and the peronei. This is the most important part of the arch, so far as its relation to this deformity is concerned. As long as the foot rests on the horizontal surface the os calcis is capable of supporting any reasonable amount of weight without the intervention of the ligaments, but if the heel is raised the body-weight is not transmitted directly through the os calcis, but the astragulus slides forward on the os calcis and throws the weight on the calcaneo-scaphoid, interosseous, and plantar ligaments. In long standing the muscles become affected, and fail to afford the necessary support to this joint, so that the ligaments stretch in time, and an extension at this astragalo-scaphoid joint takes place. In consequence of this altered relation of the pillars of the arch, the astragalus is rotated inward, so that it falls inside the plane of action of the tendo Achillis, which interferes with the action of the muscles whose function it is to raise the ankle and heel on the fulcrum of the ball of the foot. The muscles of the tibial and flexor side become relaxed, and the extensors and peronei become contracted. Whitman would, in general, formulate the cause as a disproportion between the weight which the foot is called upon to bear and the ability of the muscles to sustain it, and the simple breaking down from overwork.

---

[1] Archiv für Klin. Chir., 1880, Hft. 1, 4.

Injury of the long peroneus may give rise to this deformity without other cause, which condition Duchenne believes to be due to a functional impotence of the long peroneus. If to the enfeeblement of the long peroneus, which has been termed the check-rein of the plantar arch, there is joined the perpendicular action of the tibialis anticus, and to this is added the action of the weight of the body, the calcaneo-cuboid ligament is weakened, so that the rising of the front of the foot is not checked. The weakening of this ligament is incident to flat-foot. In painful flat-foot there is an increasing disappearance of the plantar arch, so that in inveterate cases there may be a convexity of the under surface. Gosselin claims that painful flat-foot is due to a painful medio-tarsal arthritis. That this exists has been demonstrated, but it is uncertain whether it is a primary or a secondary condition.

Pes Cavus.—This term has been given to that deformity in which the ball of the foot is approximated to the heel, converting the normal arch into a vertical sulcus and rendering the dorsum very prominent. There is usually but little power over the anterior part of the foot, and locomotion occurs mainly on the heel.

Three varieties are recognized. One is due to the peroneus longus. The characteristic signs of this deformity are effacement under the projection of the metatarsals, an increase of the plantar arch, a diminution of the transverse diameter at the level of the heads of the metatarsals, and a twist of the front of the foot on the dorsum, producing oblique folds on the plantar surface, a valgus movement in the calcaneo-astragaloid articulation, and projection of the tendon of the long peroneus below the external malleolus.

The second variety of cavus is due to paralysis of the gastrocnemius and soleus, in which the astragalus drops. In this the sole of the foot is lowered through the contraction of the long flexors, and a cavus is developed, either with or without the varus or valgus distortion.

The third variety of pes cavus has by Duchenne been designated *griffe-pied creux*. It may be acquired, but is often congenital. In either case it is due to a paralysis of the interossei and lumbricoid muscles and of the muscles which are inserted into the sesamoid bones of the great toe. By the paralysis of these, the tonic force of the muscles which extend the first phalanges and of those which close the last is not checked, and a forced extension of the first phalanges takes place, with an exaggerated flexion of the last. This depresses the heads of the metatarsals with so much force that the first phalanges are almost subluxated on the heads of these metatarsals. The plantar fascia contracts.

Duchenne claims that it is possible to confound this form of pes cavus with valgus or flat-foot, if the foot is examined while the patient is standing or walking instead of when it is in muscular repose. In the latter condition, the foot which is in the attitude of valgus touches the ground on the internal as well as on the external border, simulating flat-foot, but it may be distinguished from true flat-foot by lifting the foot. This form of pes cavus rarely produces pain in walking, and differs entirely from flat-foot due to paresis of the long peroneus.

Non-deforming Club-Foot.—Shaffer has described a deformity before not regarded as a distinct variety. In this the flexors of the ankle-joint proper are not able to perform the act of flexion, owing to the resistance of the plantar fascia or of the gastrocnemius or of both. There is generally a slight exaggeration of the tarsal arch, with little or no adduction of the tarsus or metatarsus; that is, the deformity is antero-posterior, not lateral. The ball of the foot is thus slightly approximated to the heel, the shortening being on the inner side, increasing the arch just posterior to the junction of the first metatarsal bone with its phalanx. Extension beyond a right angle is usually impossible, and with the effort to accomplish this the patient puts the toes in extreme extension.

Shaffer classifies these cases as follows: (1) those following acute poliomyelitis anterior; (2) those following simple uncomplicated malposition, habit, etc.; (3) those produced by traumatism, sprains, etc.; (4) those found after infectious diseases of children, especially diphtheria and scarlet fever; (5) those due to some remote trophic disturbance, sometimes seen associated with lateral curvature.

DIAGNOSIS.

There is no difficulty in recognizing the deformity of club-foot. In infancy a true club-foot is sometimes thought to exist when the trouble is simply a temporary spasm of the tibialis muscle which turns the foot inward; this, however, passes away in a short time.

PROGNOSIS.

Nothing need be said as to the prognosis of the deformity. It does not correct itself, and if left remains persistent as a type of obstinate disfigurement. Although club-foot is not an affection which interferes with activity or usefulness, the deformity is so marked that it is a source of great mental suffering. Dieffenbach states that of all the women treated by him only one was married, indicating that this malposition is a great impediment to marriage. Lord Byron was afflicted with this deformity, and it is said to have been the cause of Talleyrand's entering the church.

The reputed growth of a child's foot is indicated by the measurements of Quetelet and Lange, who found the feet at three months of age to be from seventy-five to eighty-five millimetres long, at six months one hundred and one millimetres, at fifteen months one hundred and twelve, at eighteen months one hundred and sixteen, at twenty-one months one hundred and nineteen, and at twenty-four months one hundred and twenty-two millimetres long: that is to say, the foot increases with less rapidity the older the child grows, and if the foot is left to itself the deformity increases greatly in the first months of life.

TREATMENT.

The treatment of club-foot varies according to the patient's age and the duration and nature of the deformity, whether congenital or acquired. The object of the treatment is the correction of the malposition and the retention of the foot in the corrected position until any return of the deformity is impossible. The treatment may be purely mechanical, or may be both operative and mechanical. Mechanical treatment requires patient attention on the part of the nurse, and in certain cases is not possible.

Congenital Cases.—Treatment in Infants.—The treatment of club-foot in infants should begin as soon as practicable, and should be instituted as soon as the child is taking its nourishment well and is free from digestive disturbance. The position of the foot should be entirely corrected before the child begins to walk, and the sooner the correction is completed the better, for as long as the malposition persists there is danger of obstinate osseous deformity. If correction by mechanical means is possible, it is preferable to operation in infants, for the reason that it is usually more acceptable to the parents. It may be done by the hand or by mechanical appliances.

The hand was recommended by Hippocrates, who advised twisting the foot outward. Later writers have advocated the same method; but the results are not encouraging, although by persistent effort on the part of the parents in cases of slight degree it may be sufficient to overcome the deformity so that at the proper age a walking apparatus may be worn. For other means, bandages, repeatedly applied, may be used, or some of the many appliances which have been devised. Many kinds of bandages have been used, but there is one object to be attained with all,—that the bandage shall harden quickly and shall be firm enough to hold the foot in the corrected position. Glue, starch, dextrin, and plaster of Paris have been tried, but the last-named has the advantage in rapidity and in strength.

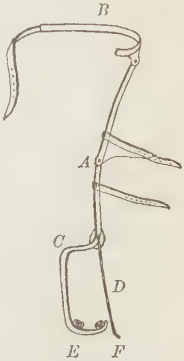
EQUINO-VARUS.—The correction of this deformity should be divided into three steps, and should be, as far as practicable, brought about in the order mentioned: 1st, bringing the foot to the outer side; 2d, raising the outer edge of the foot; 3d, bringing up the front of the foot.

It should be borne in mind that it is desirable to bring the foot from its distortion to a position in which it shall point to the outer side of the leg. The outer edge of the foot should be brought to the same plane as the inner, or even to a higher one. The ball of the foot should be so raised that the heel may strike the ground first.

If it is attempted to correct the distortion by daily manipulation, the foot should be grasped with the sole in the palm of the hand, the fore-part of the inner border pressing against the ball of the thumb, the fingers over the dorsum, and the foot gently everted, abducted, and flexed. To do this the right hand must be used for the left foot, and *vice versa*. No limit can be made to the extent to which this should be employed, but only persistent effort will be successful, and it is unwise to attempt this method unless the physician is sure of intelligent aid from the mother or nurse, and then only in cases of slight degrees of deformity. Mechanical appliances will be necessary later, as after correction by other means.

BANDAGES.—Correction by bandages is the same in principle whether plaster or other material is used. The foot must be well protected by cotton, care being taken to insert small pieces between the toes, and the bandage should extend from the toes to a little above the knee. Considerable correction may be obtained while putting on the bandage by so adjusting the turns as to pull the foot into the desired position, but reliance must be placed mainly upon the forcible holding of the foot in as nearly as possible a corrected position while the plaster is hardening. The bandages should be renewed every two or three weeks until the foot is so far corrected that a retentive appliance can be worn.

FIG. 4.



Beely, of Berlin, has devised an apparatus which is useful in correcting the deformity in infants, and may be used in place of the bandages. It is shown, slightly modified, in Fig. 4. It consists of a steel strip, *A*, jointed at the knee and hip, with a band which encircles the pelvis, *B*, and is secured to the outer side of the leg by straps above and below the knee. At the ankle this is made to pass in front of the leg *C* to the other side, and is then continued downward and bent so as to pass beneath the foot. This portion is provided with two buckles, *E* and *F*, which are attached to adhesive plaster applied to the leg in much the same manner as for extension in hip-disease, and serves to keep the foot from slipping up away from the appliance. At the point where the upright turns to cross the ankle is fastened a rod of soft tempered steel, *D*, which projects downward and forward and is bent to suit the direction in which the pull is to be made. Adhesive plaster is then wound round the foot at the level of the ball of the toes, in the direction of over the dorsum to the inside and under the sole, and the end is fastened to the extremity of the spur. By this means the deformity should be corrected in a few weeks, after which a retentive shoe will be necessary. The apparatus applied is shown in Fig. 5.

FIG. 5.

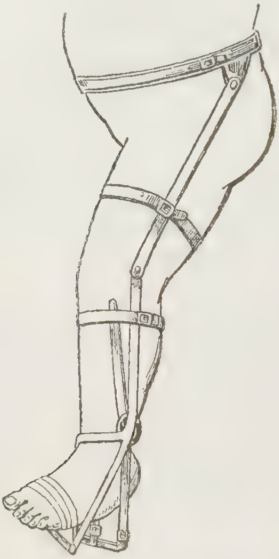


FIG. 6.

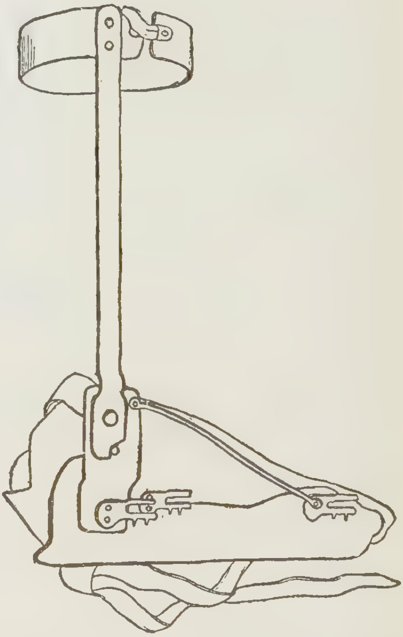
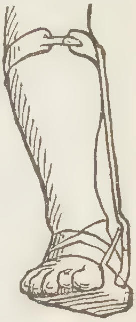


For correction by mechanical means Taylor's club-foot shoe has the advantage of being simple and easily applied. It is useful for slight degrees of deformity or after the foot has been nearly corrected by other means, but its greatest value is in its use as a retention apparatus. It is shown in Fig. 6, and consists of a piece of steel fitted to the shape of the sole, with an upright on the inner side, and provided with an ankle-joint so arranged by a stop as to arrest flexion at a right angle. In applying the apparatus the sole is pressed firmly into the shoe, and the foot held in its place by the straps and buckles. To do this it is necessary that the upright should be bent forward, and it will then lie obliquely across the leg. This should then be carried into its position on the inside of the leg and secured by the strap at the upper extremity, which is for that purpose. By this motion the foot is brought forcibly into position. It is important that the heel should be retained well down on the sole-plate, but occasionally it is difficult to accomplish this. It may, however, be done by applying adhesive plaster to the leg and securing it to buckles at the heel of the shoe before carrying the upright into position. The foot in position is shown in Fig. 7.

FIG. 7.



It often happens that there is an obstinate tendency in the toes to turn in or out: this is beyond the control of the patient, and it becomes necessary to overcome it by means of apparatus. This protection is more obviously necessary after operation, and may be easily accomplished by extending the upright to the pelvis, to which it may be secured. The arrangement is shown in Figs. 8 and 9.

This case was one of extreme deformity, as shown in Figs. 10, 11, and 12. One foot was corrected by the employment of extreme force, the other by the same method with the addition of astragaloid osteotomy. The result after four weeks is shown in Fig. 13.

FIG. 8.

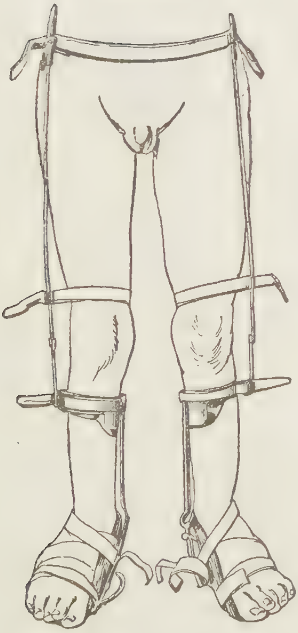


FIG. 9.

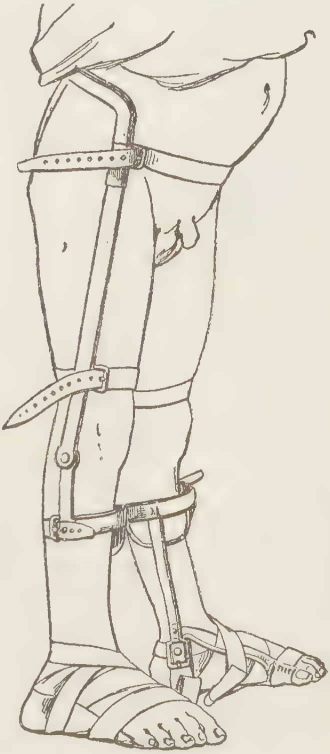

In many cases mechanical treatment alone fails to effect a cure, and division of the unyielding structures becomes necessary. Tenotomy is required because the muscles are powerful structures, but their division is not an essential part of the treatment. It is a mistake to divide the

FIG. 10.

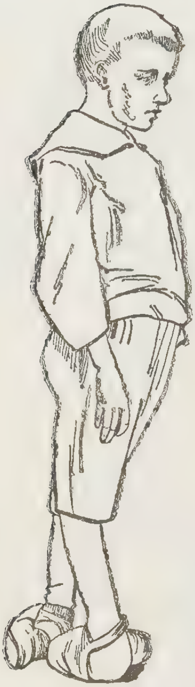

FIG. 11.

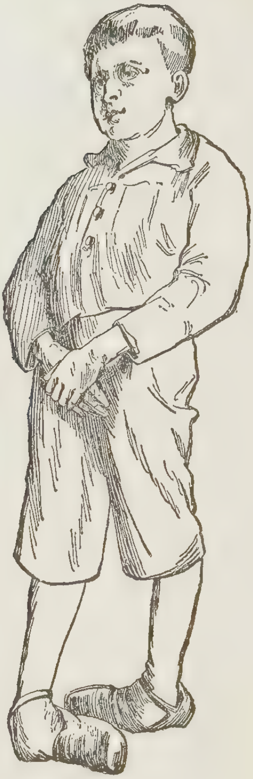

FIG. 12.

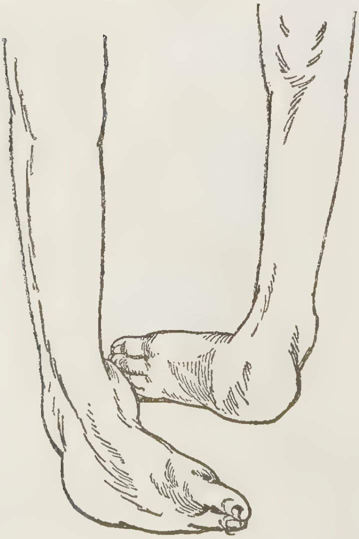

FIG. 13.

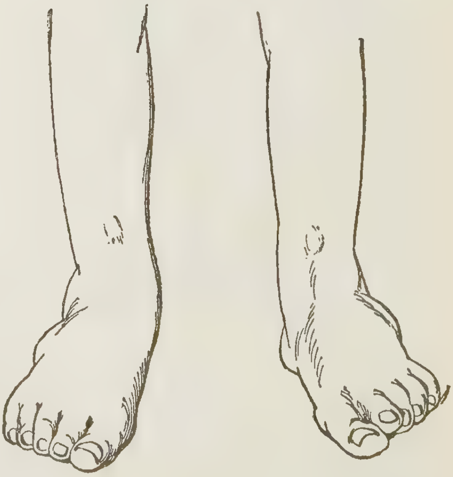


tendons according to any fixed plan or rule, the only wise course being to wait till the progress of the foot towards rectification indicates that some structure must be cut. Division of anything except the tendo Achillis is rarely necessary, and this should not be done until after the foot has become unfolded, so that the deformity has become an equinus.

Some writers, however, advocate division of the shortened tendons and ligaments before the mechanical treatment. The age at which patients should be operated on is a matter of discussion. Some assert that it should not be done before the end of the first year, others that it is advisable to interfere as soon as possible. Stromeyer operated on an infant twenty-four hours old. In some cases division of the calcaneo-scaphoid ligament is necessary. After tenotomy the foot should be forcibly straightened, so that any remaining fascia or shortened tissue shall be torn or stretched, and it is absolutely necessary that the foot be over-corrected. It can be placed in this position in a fixed bandage, and allowed to remain until the incisions have healed. This practice is not recommended by some surgeons, on account of the fear of non-union of tendons; but clinical experience warrants the statement that such fear is groundless, and much time and discomfort of the patient are saved by this procedure. The details of the operation are described farther on. For fixation the writer prefers the application of silicate-of-potash bandages directly to the foot, which is first protected by a layer of sheet wadding, or by a bandage neatly applied so as to avoid wrinkles. Over the silicate, which requires two or three days to harden, a plaster-of-Paris bandage is wound. If this is properly made, it becomes stiff in a few minutes. In three or four days this can be cut away, leaving the hardened silicate bandage, which is light and not clumsy.

Both the silicate and the plaster-of-Paris bandage should be applied above the knee, with the knee slightly flexed, otherwise an inversion of the foot will take place. While the plaster is hardening it is essential that the foot should be held well corrected, otherwise the desired amount of over-correction will not be obtained, and a second operation or subsequent mechanical treatment will be required.

There are two objections to the use of fixed bandages,—the danger of sloughing of the skin, and the impossibility of further correcting the foot from the position in which it has been placed. The first objection may be avoided by skill in applying the fixed bandages; the second must be made as slight as possible by care to correct fully while the plaster is hardening. Mechanical means to complete the correction are rarely necessary if the operation is properly done, but the use of a retentive appliance is required till the child walks with the foot in a perfectly normal position, which may be a long time.

TREATMENT OF OLDER CASES.—Of the treatment of this deformity in older children, who are able to walk, very much the same may be said as of that in infants, except that mechanical correction is much more tedious, and therefore operative means are to be preferred.

In children of five years and upward there is required, as a rule, the use not only of the tenotome, but also of considerable correcting force. Mechanical means alone require much patience on the part of the surgeon and much time on the part of the patient, which can be avoided by the use of the tenotome and a forcible correction, while with older, relapsed, and resistant cases still more difficulty is encountered.

Of the treatment of club-foot by the employment of apparatus, Panas speaks as follows: "The results obtained by the employment of appliances alone not only leave a great deal to be desired, but in a small number of fortunate cases when the cure has taken place it is only attained at the price of a great deal of suffering and a very long time, several months or one or two years, and sometimes more."

This difficulty lies partly in the firm condition of the tendons, fascia, and ligaments, and partly in the amount of distortion of the tarsal bones. Simple tenotomy will not ordinarily suffice to overcome the distortion, but combined with the use of force may, if persisted in, result in a cure, although in some cases, even with the successful employment of mechanical force, a great deal of time is required.

Operation.—For operative measures the following are open for choice: tenotomy, open incision, use of extreme force, tarsal osteotomy, tarsal resection.

No definite rule can be laid down for the application of the above procedures, but in general it may be said that the simplest methods should be first considered, and the others used only as in each case the indications for extreme measures present themselves.

Tenotomy.—Tenotomy is one of the simplest and least weighty factors in the treatment of club-foot, but it should be regarded as merely an adjunct to other means. Applied for the first time in the treatment of congenital torticollis, it was practised later by Lorenz, Sartorius, and Michaelis for club-foot. Delpret, guided by accidental section and rupture of the tendon, was the first to divine the indications for a scientific tenotomy, and Stromeyer, Bouvier, and Guérin have made the operation indispensable.

In the section of muscles of the foot, one proceeds differently according to the case, sometimes making the incision from the skin towards the tendon, and sometimes passing the tenotome underneath the tendon and cutting towards the skin. Bouvier calls the two methods of procedure sub-tendinous and supra-tendinous section. According to many surgeons, the choice is a matter of indifference, but the sub-tendinous method is sometimes to be preferred as the simplest in its execution, and as permitting complete section of the tendon without risking the skin. The supra-tendinous method is to be preferred where the tendons are not very salient, as in young children, or where they lie close to bone or in the neighborhood of vessels and important nerves.

The reparation of divided tendons has been made a subject of numerous investigations since Hunter's original experiments in 1767. After division the cut ends are separated to a variable extent, depending on the length of the muscle to which the tendon belongs, on the position in which the limb is placed, and on the surrounding attachments of the tendon. There extends between the cut ends a tubular sheath of active tissue, which chiefly furnishes the reparative material. This sheath becomes vascular, and after the absorption of any blood that may have been effused within it the interval between the divided ends of the tendon becomes filled with lymph, which gradually becomes fibrillated and forms a firm bond of union between them. The new material so closely resembles the old tendon, and is so intimately blended with it, that for a time it would be difficult to distinguish them, except for a certain translucency which is possessed by the former and is not natural to the latter. The tendon is thus increased in length to the extent of the interval by which its ends are separated. The separation should not be maintained at its full extent at once, lest the uniting medium be thin and weak, but should be gradually produced by altering the position of the limb.

The time occupied in obtaining the required elongation varies from two to six weeks, according to the activity of the repair and the severity of the case, and with proper operative procedure with a healthy subject a perfect use of muscle of normal length is obtained. Doubtless adhesions often form between the divided tendons and the surrounding structures, but in ordinary cases they are not of the least consequence, for they give way to the manipulation or use of the foot, and do not interfere with the function of the muscle.

Section of the Tendo Achillis.—The patient should lie on his face, an assistant holding the foot. Having made a longitudinal fold of the skin, the surgeon enters the knife parallel to the border, passing it flatwise between the tendon and the skin. The blade of the knife is then turned towards the posterior surface, and by pressure of the left index finger on the skin over the back of the tenotome the sensation of the cutting of the tendon can be felt. The assistant should raise the end of the foot, so as to make the tendon somewhat tense during the section. The only protection necessary is to be assured of complete division.

Section of the Tibialis Posticus.—If the muscle is to be divided in the leg, the foot is placed on its external border. The surgeon divides the skin by means of a pointed tenotome two centimetres above the tip of the internal malleolus, and on a vertical line situated half-way between the posterior border of the malleolus and the corresponding border of the tendo Achillis, and passes the tenotome perpendicularly downward to the depth of ten or fifteen millimetres. The handle of the instrument should then be turned so as to describe the arc of a circle, and the tendon divided vertically inward. The tenotome is then withdrawn and a blunt-pointed one inserted. This should be so directed as to pass behind and under the tendon, and it is then sufficient to turn the cutting edge forward and to move the instrument gently forward and back, the assistant at the same time turning the foot in the direction of abduction. It is essential, in order to avoid wounding important parts, to adhere strictly to the rules laid down. If the incision is made too near the malleolus, the internal saphenous vein may be opened, and the nerve of the same name may be cut. If the incision is made too near the tendo Achillis, there is danger of dividing the tendon of the long flexors of the toes and the posterior artery and nerve. Bonnet thinks that he has wounded this artery more than once, but without serious injury. To avoid this possibility, Velpeau advised cutting this tendon in the foot, in a line from the top of the internal malleolus to the scaphoid; but this is not easily done in infants.

Section of the Tibialis Anticus.—The division of this tendon is more easy, and it is sufficient to be guided by the prominence of the tendon put on the stretch by abducting the foot. To avoid wounding the deep parts it is better to enter the tenotome under the tendon.

Division of the Plantar Fascia.—It is advised by some writers to divide the plantar fascia before the tendo Achillis, as the latter acts as a support for stretching the foot when the fascia is divided. No fixed rules are necessary for this operation, but the tense fascia should be felt, the tenotome inserted subcutaneously, the blade turned inward, and the division made with care. Walsham[1] reports the appearance of an aneurism as large as a marble two weeks after this operation in a boy of seven. It was cured by pressure maintained for two months over the posterior tibial artery.

Many times the tenotomy combined with forcible correction is not sufficient to complete the restoration of the foot to the normal position. The obstacle is often the resisting fascia, which cannot be thoroughly divided subcutaneously. In such cases section by open incision may be performed.

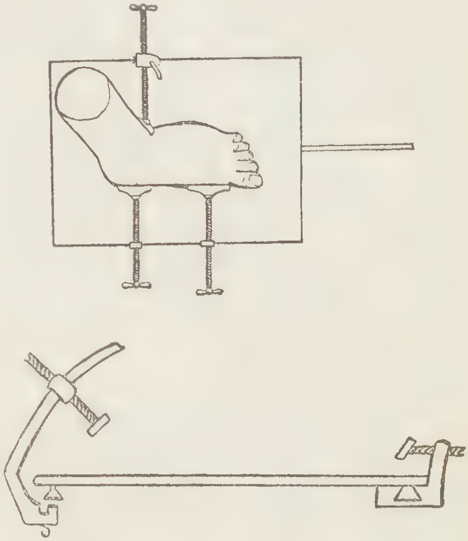
Open Incision.—The advantage of this operation in club-foot is the facility of complete division of all the soft tissues. The method is as follows. An incision is made along the inner side of the foot from the top of the malleolus well down to the inner edge of the first metatarsal bone. After the skin the other tissues are divided with care, using a director if necessary. The tibialis tendon is cut across at its insertion, and the plantar fascia is divided by a tenotome or a long thin knife. The artery can be spared by careful dissection, but may be sacrificed if necessary. A cross incision towards the sole of the foot from the middle of the long incision is sometimes essential, but it is desirable, if possible, to avoid this. The foot is then brought into as normal a position as possible, thorough aseptic dressings are applied, and the foot is fixed in a plaster-of-Paris bandage.

Use of Extreme Force.—By this is meant the application of such force, in the direction of correcting the deformity, that the ligaments are torn or stretched; and this should be done under an anæsthetic. The chief difficulty is that of applying the force directly, as, owing to the shape and size of the foot, it is almost impossible by the use of the hands alone to twist the foot in such a way as to stretch or tear the resisting ligaments. An apparatus has been devised for this purpose by Dr. T. G. Morton, of Philadelphia, a modification of which is indicated in the accompanying diagram (Fig. 14). The object of the appliance is to exert pressure, under control of the operator, in three directions, and also to enable him to twist and raise the front of the foot. It is inapplicable to small children.

---

[1] Lancet, January 28, 1888.

Fig. 14.



The apparatus consists—

1. Of a plate large enough for any foot.

2. Of three steel buffers or padded plates which are attached at the ends to steel screw rods playing through sockets with a female screw thread at the sides of the large plate. By turning the screws, which is done by the handles, the plates or buffers are pushed forward. They should be placed so as to press (1) upon the side of the first metatarsal, (2) on the side of the os calcis just beneath the inner malleolus, and (3) on the outer side of the foot over the projecting head of the astragalus. The female screw through which the male screw plays is adjustable upon an arm curved so that pressure can be applied when it may be found necessary.

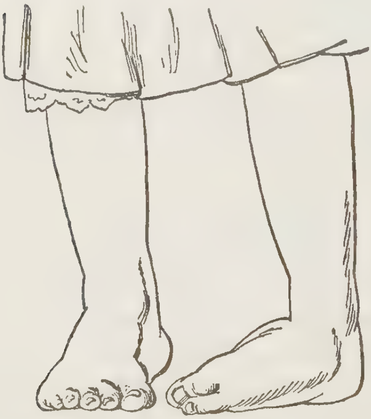
The sockets and arms are arranged so that they can be shifted and placed at any point along the side of the large plate, or can be shifted from side to side, so that the appliance can be used for either foot.

3. A straight rod, extended in the plane of the plate, gives increased power in raising the front of the foot. This is not always needed, and can be removed.

The procedure in this method is as follows. Tenotomy is performed in the usual way, the plantar fascia being divided first, then the tendon of the tibialis posticus if necessary, and, after the deformity at the arch of the foot has been in a degree corrected, the tendo Achillis. The foot is then forcibly manipulated with the hands, pressure being exerted in a direction to overcome the deformity. If this is not sufficient for correction, the instrument is to be applied so that the screws will press on the foot as described. The correction will be done gradually, although at times the fibrous tissues will be felt to tear. An assistant steadies the leg, and the operator first attempts to change the varus into a valgus, without reference to the equinus. By turning the plate outward or upward the twist of the foot and the equinus can be corrected. The skin on the inner side of the foot frequently becomes tense, but the danger of its rupture is not a practical one. In many cases the correction may be accomplished at once, but if much resistance is encountered it is best to use some time, and allow the stretching to be gradual. The foot should then be put into a plaster bandage, and firmly held until the bandage is fixed.

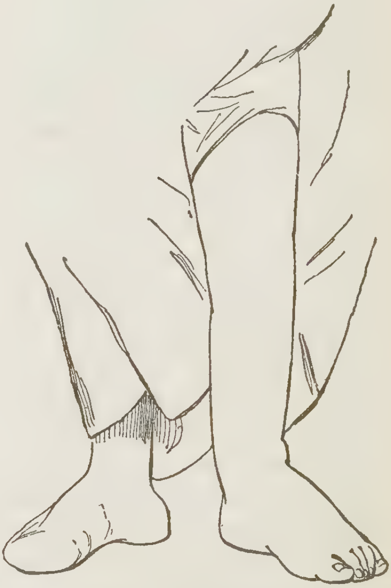
The objections to this forcible correction after tenotomy are chiefly theoretical, no ill results having been known to follow. The injury done to the foot is not greater than that of a severe strain, and the patient is given the advantage of a painless correction and rapid cure. An objection which is sometimes raised against this method is the supposed risk, but this is not so great as would be thought. Experience with osteoclasis has proved that the temporary pressure on the skin does not cause sloughing, or even an abrasion, and the same is true with this operation.

Fig. 15.



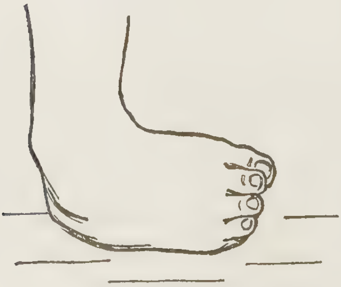
Girl of eighteen treated by the method of extreme force.

Fig. 16.



Result in the same case.

Fig. 17.

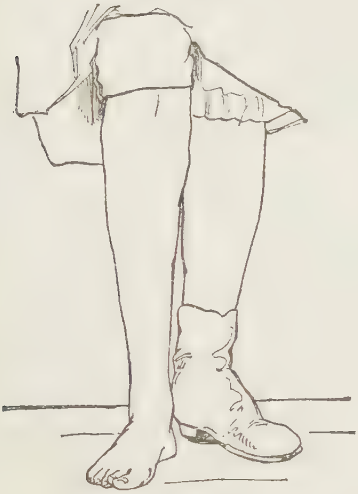


Figs. 15 and 16 show the condition of the foot before and after treatment by this method.

Fig. 17 is a drawing from a cast of a foot in every way similar to the above: the result of treatment by this method is shown in Figs. 18 and 19.

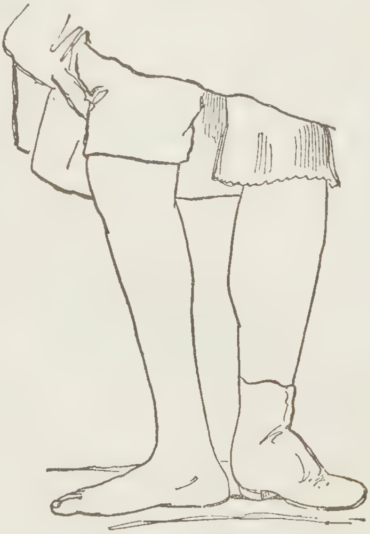
Tarsal Osteotomy.—In certain cases the distortion of the bones is so great that no operative procedure directed simply to the ligaments and tendons will be sufficient permanently to correct the deformity; but, fortunately, cases of this kind are rare. To meet such a condition either osteotomy or resection of the tarsal bones is required. The most important condition lies in the distortion of the astragalus, and especially in its neck, and it is against this part that the operation is usually directed.

FIG. 18.



Result, front view.

FIG. 19.



Result, side view.

The simplest way of doing this operation is through an incision down to the bone, from the tip of the inner malleolus to the inner side of the head of the first metatarsal bone, which will be found in severe cases close to the malleolus. The incision is close to and nearly parallel with the tibialis anticus tendon, and in the direction of the metatarsals. The scaphoid will be seen before the astragalus, and will be always first within reach of the knife. The foot is then straightened, which separates the scaphoid from the malleolus, and, if still further straightened, the scaphoid begins to uncover the astragalus, and the neck is seen. A small osteotome is entered on the neck of the astragalus to the distal side of the scaphoid articulation, and the bone divided, or nearly so, after which the fracture is completed by forcibly straightening the foot. The section should be at such a plane that when the equinus deformity is corrected the gap at the section shall be as small as possible. A fixed bandage is then applied, with the foot in a corrected position.

Tarsal Resection.—This operation should be resorted to in the most resistant cases only. Excellent results are obtained by this method, and the danger is not great, but undoubtedly both by cuneiform resection and ablation of the astragalus a great deal of bone is removed unnecessarily, and the foot is considerably shortened.

The following methods may be used: enucleation of the cuboid and the astragalus, with or without removal of the end of the external malleolus;

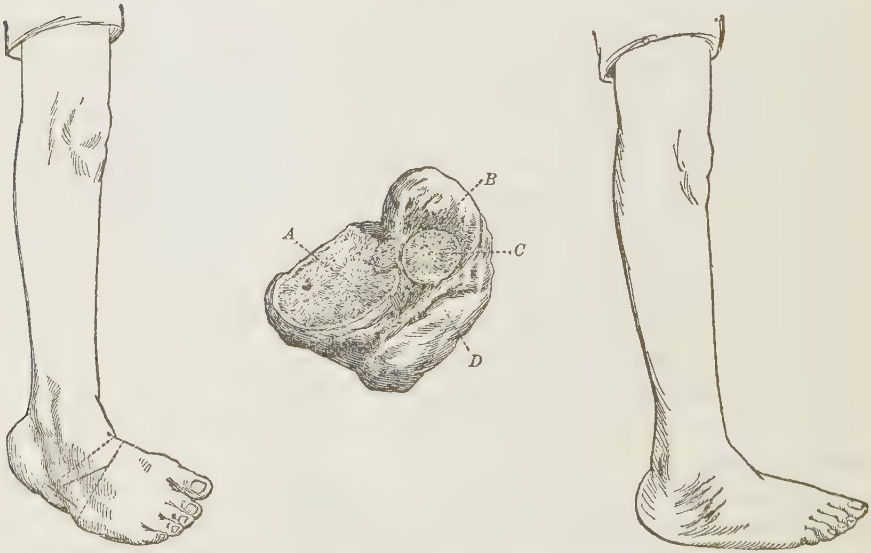
removal by curette of a portion of the astragalus, leaving the cartilaginous surfaces untouched; enucleation of the astragalus, the cuboid, and the scaphoid, or simply of the scaphoid and the cuboid; enucleation of the head of the astragalus, or resection of a portion of bone on the outer side of the neck; resection of the wedge-shaped portion of the bone at the medio-tarsal articulation.

Of these methods but two will be likely to come into general use,—the removal of the astragalus and the wedge-shaped resection of the tarsus. Enucleation of the astragalus is sufficient to enable the foot to be brought to a right angle, except in rare cases where the calcaneus is entered to the posterior surface of the tibia. Supination of the calcaneus can be cured by removal of the astragalus, though in severe cases the end of the fibula must also be removed; but supination of the whole foot is not directly cured by this procedure, although correction by appliance is rendered more easy. In severe adult cases more bones have to be removed.

Excision of the Astragalus.—Ablation of the astragalus is best done by Hocher's method, in which an incision is made back of the external malleolus down to the outer side of the foot, the peroneal tendons divided, and the foot forcibly twisted to the inner side. The astragalus is thus brought into view.

Excision of a Wedge-Shaped Piece.—An Esmarch bandage is applied to the foot, and an incision made along the entire border of the foot from the middle of the os calcis to the middle of the fifth metatarsal bone. This is joined at right angles by another across the dorsum of the foot. (Fig. 20.) The soft parts being reflected, the cuboid is first removed, and a wedge-

FIG. 20.

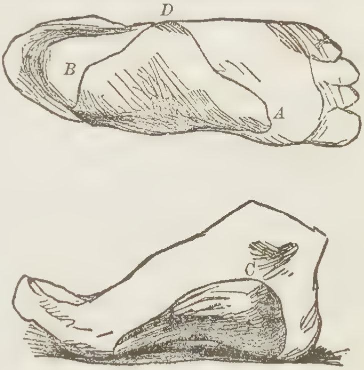


Excision of wedge-shaped piece. (Bryant.)—*A*, calcis; *B*, scaphoid; *C*, astragalus; *D*, cuneiform.

shaped portion of the tarsus is then excised, of sufficient size to allow the foot to be brought into position without much force. The wedge, which may be removed with a chisel or saw, should have its base of a width corresponding to that of the cuboid, and should be rather thicker above than on its lower surface.

FLAT-FOOT.—The principle in the treatment of this deformity consists in the restoration of the natural arch, but the method of accomplishing this necessarily varies with the case. In acquired forms mechanical means are sufficient in most instances. Whitman advises a light steel plate (Fig. 21), slightly elastic, which reaches from just behind the ball of the great toe, *A*, to just in front of the bearing point in the heel on the inner surface of the foot, *B*. It should run just above the head of the astragalus, *C*, which carries it nearly to the internal malleolus, and extend under the sole of the foot just behind the fifth metatarsal, *D*. The plate must be fitted from a cast of the foot taken with the foot in a restored position. When the weight is put on the properly-shaped plate, not only is the arch of the foot held up, but the inner flange of the plate acts as a lever pressing up against the sustentaculum tali and the tuberosity of the scaphoid.

FIG. 21.



This support is particularly useful in acquired cases in adults, and it has the advantage of allowing natural motion to the foot. Light cases, particularly in children, do very well with a plate of thin steel fitted to the shape of the sole and elevated on the inner border to conform with the normal arch of the foot.

The elastic extension applied so as to support the arch of the foot has been advised by Barwell; but it requires considerable care on the part of the patient, and accomplishes no more than the supports described.

In congenital cases and in some of the severer instances of the acquired deformity, although the same mechanical treatment is required, other means may be necessary to bring the foot into a position in which support would be of value. Forcible restoration of the foot and fixation for a time will be sufficient in some cases. Duchenne thinks that the only muscle which can be contracted is the short peroneus, and that section of the long peroneus in valgus is not feasible. Ogston refreshes the astragalo-scaphoid articulation and nails the bones in a corrected position, and Stokes[1] removes a wedge-shaped piece from the inner side of the neck of the astragalus; but it is very seldom that these severe procedures will be required. Usually restoration of the foot to its normal position, followed by a period of rest and the fitting of some proper support, is all that will be needed.

---

[1] Transactions of the Academy of Medicine of Ireland, 1885.

VALGUS.—There are three things to be done in the treatment of valgus, —the elongation of the shortened structures, the overcoming of the distortion, and the promotion of the function of the limb.

In infants manipulation may be all that is necessary, or the foot may be corrected forcibly and retained by plaster until a normal position is obtained, after which a retentive appliance can be worn. These cases, if taken early, rarely give much trouble.

In older and acquired cases a supporting appliance is necessary. It may be sufficient to retain the foot in an inverted position by means of plaster or bandage, but more often some form of external appliance is needed. For this an excellent support is obtained with Taylor's club-foot shoe reversed and applied to the outside of the foot, with a strap passing from the upright round the leg over the internal malleolus and secured again to the upright. By this the eversion of the foot at the ankle-joint can be controlled.

Tenotomy of the peroneus may, however, sometimes be necessary.

TALIPES EQUINUS.—It is seldom that the surgeon is required to do more in the congenital cases than to overcome this deformity by simple manipulation or by fixed bandages, although tenotomy will save time.

In neglected and acquired cases section of the tendon and the application of a retention shoe are required.

TALIPES CALCANEUS.—In the simple forms of the congenital variety little more is needed than manipulation. If the deformity persists, a retentive appliance which prevents extension to the desired limit may be worn. If the deformity is severe and resistant, tenotomy of the tendons of the anterior portion of the foot, especially the tibialis anticus, may be required. Excision of a portion of the tendo Achillis is of benefit in more advanced cases, although this procedure is by some writers considered unnecessary.

PES CAVUS.—Restoration of the foot to a natural position in cases of pes cavus is hardly possible, as they have usually existed for a long time when first seen by the surgeon, and have become very resistant. If restoration be attained by operative means, mechanical treatment will still be necessary for a long time, if not always, as the condition is paralytic in its origin and will tend to recur if the foot is left unprotected. The best form of apparatus is the Taylor club-foot shoe, fitted with a stop-joint the reverse of that used in equinus, if there is much tendency to calcaneus deformity.

TORTICOLLIS.

By E. H. BRADFORD, M.D.,

AND

E. G. BRACKETT, M.D.

Synonymes.—Wry-neck, Caput obstipum, Collum distortum; French, Cou tors; German, Schiefhals.

The name torticollis is given to that distorted position of the head in which it is held awry. This condition is either congenital or acquired, and may be constant or intermittent. The affection involves a contraction, tonic or clonic, of the muscles of the neck, usually those of one side alone, but occasionally of both sides. The position of the head varies with the muscles affected, those usually involved being the sterno-mastoid, the anterior edge of the trapezius, the scaleni, the platysma, and the splenius capitis.

Males are more subject to wry-neck than females, and the right side is oftener the seat of the affection than the left. In thirty-seven cases collected by Dieffenbach five were on the left and thirty-two on the right side.

CONGENITAL TORTICOLLIS.

The true congenital form is very rare. A few cases have been noticed in which an imperfection in the atlas and cervical vertebræ existed, in consequence of which the head was held in malposition. An intra-uterine origin is assumed by some writers, but without other than theoretical reasons. A case has recently been reported[1] of this deformity occurring in a still-born infant, which was caused by a shortened condition of the trapezius and sterno-mastoid muscles, but the distortion could not be entirely overcome until after section of the supra-spinous and interspinous ligaments; but such a condition is one of great rarity, and the author states that no analogous case could be found. One case accompanied by unilateral atrophy of the head has been reported.[2] In a certain number of instances the so-called congenital wry-neck is due to injury at the time of birth, either from forcible stretching of the muscles or from traction in difficult labor, with a rupture of certain fibres of the sterno-cleido-mastoid. Examination will show this muscle to be contracted, and careful palpation will reveal that a portion of the muscle has been torn, and that the spasm of the internal portion gives rise to the distortion.

ACQUIRED TORTICOLLIS.

Acquired wry-neck presents several forms, their distinction being based on the etiology rather than on any essential difference in symptoms. These may be classed into spastic, paralytic, compensatory, idiopathic, and those following fracture or dislocation.

The *spastic* may be due to direct nerve-irritation, either central or along the course of the nerve, or it may be the local manifestation of a more general nervous irritation, as in spinal irritation: these, however, are very rare. Arising from a local neighboring disease it is more frequently met with. Conditions causing this are disease of the cervical vertebræ, enlarged cervical glands, deep cervical abscess, etc., being analogous to muscular spasm around other joints.

Paralytic.—This form is rarely met with, but may occur from unantagonized muscular action after paralysis of muscles of one side, which may result from central or peripheral cause; but this should not be regarded as true wry-neck. Any deficiency of nervous tone, although not causing actual paralysis, and such as may result either from direct nervous influence or from overwork of one particular set of muscles, may result in a spasmodic condition of the corresponding group from failure of proper antagonism. Several instances of this have been observed.

Compensatory.—Various examples of this have been noted where the head has assumed an abnormal position in consequence of some existing inequality or deformity. Instances of this are seen in some lateral curvatures, in which the relation of the head to the shoulders is distorted in the effort to keep the head in an upright position. Wry-neck has also been observed as the result of inequality of the two eyes, although this is usually compensated by accommodation. Quignet has termed this "torticollis oculaire."

Idiopathic.—In many cases, such as come under this head, there is obviously no lesion to explain this pathological condition, but it occurs as the result of general malnutrition, having this as a local manifestation. Not infrequently in these cases there will be found a definite exciting cause, such as fright, grief, etc. In this class are also included those acute cases which are due to an inflammatory condition of the muscle itself.

Many of the above causes seem to be but one or more of many factors. In a large percentage there will be found a neurotic family or personal history. The general condition seems also to have a very considerable influence, many cases occurring after severe overwork. Excessive use of the muscles of one side has in several instances apparently occasioned attacks, as in seamstresses who have worked on heavy material, and one case has been reported in a factory-girl whose occupation required her to turn her head frequently to one side. This position is sometimes assumed when the condition can hardly be considered pathological. Bouvier states that voluntary torticollis is habitually connected with different temperaments, and, in fact, the position is a means of expressing emotion.

PATHOLOGY.

In the acute form of torticollis there is nothing to be said as to the pathological anatomy.

In the chronic forms such changes occur as result from long-continued malposition or disuse. Fibrous degeneration, adaptive shortening, loss of tonicity, and over-stretching take place in the muscles, as well as shortening and lengthening of the fascia around the bones. Alteration in size of the bodies of the vertebræ occurs in a certain number of instances, but this osseous deformity is not so common as would be supposed, and is denied by Bouvier.

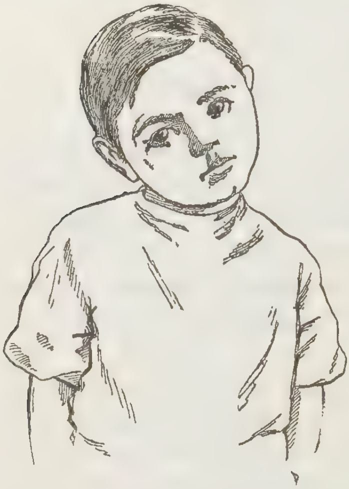
Other changes noted are cervical spinal curves with a compensatory curve in the dorsal region, shortening and secondary affection of other muscles than those involved in the spasm, asymmetry and difference in length of the clavicles, and asymmetry of the face, the long axis of the face striving, as it were, to gain a vertical position not possible to the head. This gives a deviation of the line of the nose from the ordinary line of the eyes. Furthermore, the two eyes and the two commissures of the lips are not of the same size, the cheek on the contracted side is less prominent, and the features on that side are smaller. This asymmetry diminishes, however, if the deformity is corrected at the proper time. Dubreuil asserts that the cranium itself also indicates a change, and that inequality of the cerebral hemispheres results. Broen concludes from this that a diminution in intelligence would necessarily result; but this is contrary to clinical evidence.

The affection involves essentially, in the great majority of cases, the distribution of the spinal accessory nerve. Conditions causing paralysis of this nerve indicate the same area to be affected, the sterno-mastoid and the upper part of the trapezius, that which passes between the occiput and the acromion. The former receives only a few unimportant filaments from the cervical nerves, while the latter has branches from the cervical and the dorsal nerves distributed to its lower portion. These muscles are most frequently affected, and the sterno-mastoid more frequently than the other: it is, however, rarely affected alone, but, being a terminal muscle, its contraction is more usually noticed than that of the others. Bouvier found that in three cases out of four the sternal branch was the only one contracted. Delore believed that the posterior muscles of the neck were the chief ones affected; and they certainly are affected secondarily, if not primarily.

SYMPTOMATOLOGY.

The congenital form is perhaps without exception of the tonic form of spasm. The condition is noticed soon after birth, and the deformity alone calls attention to the affection. On examination, the sterno-mastoid and possibly a portion of the trapezius will be found contracted, and in cases due to injury of the muscle palpation will often reveal the site of rupture, but later the deformity alone exists. Here a true shortening of the muscle is the cause of the deformity. (Fig. 1.)

FIG. 1.



The usual attitude in the so-called congenital cases.

The acquired form is either acute or chronic. In the acute variety the history is that of acute muscular rheumatism, with some constitutional disturbance. There may be pain in the neighborhood of the affected muscles and their insertions. Any motion, and especially a sudden one, is particularly painful, and to prevent this the head is held rigidly on the shoulders by muscular spasm, the patient turning the trunk and the head together.

The position assumed is essentially the same as in the chronic variety, which is described later. The duration is of a few days only, but some stiffness may remain for a week or more.

Ordinary "stiff-neck" must be considered as a mild form of this affection, but involving the deeper structures.

The chronic form may develop from the acute, or may be of gradual development from some unknown cause. Congenital cases are also usually chronic.

The position assumed by the head depends on the muscles affected. When the sterno-mastoid is attacked, the ear of the affected side is brought nearer the sternum, the face turned and slightly rotated to the opposite side, and the chin elevated above its normal level. The features may be drawn below those of the opposite side, while in severe and especially persistent cases the jaw is rotated so that the teeth cannot be approximated. In proportion to the extent to which the trapezius is affected the head is drawn towards the shoulder, and when this muscle alone is involved the head is drawn backward and towards the shoulder, which occurs in posterior torticollis, described chiefly by Delore, who declares it to be the more frequent form. In this the other posterior muscles are involved in the spasm. (Figs. 2 and 3.)

Physiologically, the splenius if contracted would draw the head to the side and turn the face to the same side; but this, according to Delore, never takes place in torticollis, and it is therefore assumed that the splenius and the sterno-mastoid never are affected on the same side. When the levator anguli scapulæ is affected together with the sterno-mastoid, there is an increase of the lateral obliquity and of the rotation.

Combinations of different muscles have been observed, but are of infrequent occurrence. Such are a combination of the contraction of different muscles on different sides, a simultaneous contraction of the splenius and the levator anguli scapulæ, of the scalenus anticus and the splenius, of the two platysmas, and of the sterno-mastoid on one side and the splenius on the other.

Fig. 2.

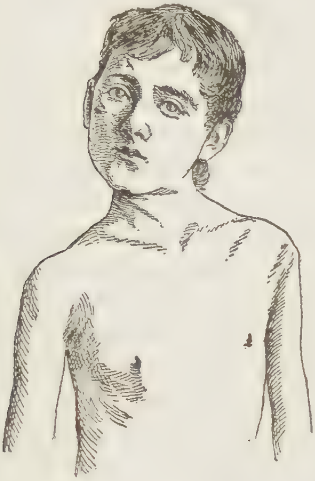


Fig. 3.

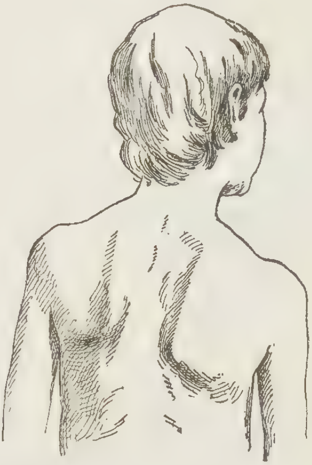


Torticollis of several years' duration.

The attitude is the most characteristic feature of this form of the affection. On palpation certain muscles will be found hard to the touch and others flaccid. Bands of contracted fascia are frequently seen in old cases. There is no pain, but attempt to rectify the deformity is painful if persisted in. Rotation of the head is free within certain limits. A deviation of the spinal column—a lateral curvature with rotation—necessarily follows torticollis. In order to retain the head in the vertical position, the patient, unable to twist the cervical spine, will twist the trunk, raising one shoulder, which is accompanied by a complete rotation of the vertebræ and projection of the ribs backward on the concavity of the lateral curve. Although the head is twisted, strabismus rarely results, and although the movement of the larynx in extreme cases is apparently limited by the distortion, the voice is not affected for speech. A slight difference of the surface-temperature has been observed, it being lower on the affected side.

Paralytic cases differ from the above, as the condition is one of unantagonized action rather than of spasm. The patient cannot move the head nor produce any prominence of the muscles on the paralyzed side. The surgeon can easily correct the deformity, meeting with little resistance, unless the case is of long standing and retraction of tissues on the opposite side has occurred.

A variety of torticollis called by Dally occipito-atloidian has been described, as follows. Its development is usually due to rheumatism. It is characterized anatomically by a subluxation of the atlas on the occipital bone in such a way that the lateral masses are transverse to the vertical plane. Clinically there is a projection on the transverse process posteriorly. There is a spiral torsion of the head which may resemble muscular torticollis. This may afterwards result in a bony ankylosis.

The spasmodic or clonic form usually begins later in life. It may be unilateral or bilateral, and, as in the other form, there are very slight subjective symptoms, except the pain caused by the cramp. However, there may be occasionally a sense of uneasiness in the back, and later, after the friends have noticed that the head is not held straight, there may be pain near the insertion of the sterno-mastoid. In other cases slight twitching of the muscles is observed for some time previous to an outbreak of the spasmodic condition. In some instances the head can ordinarily be held in proper position, but locomotion, any excitement, or the apprehension of being observed will produce such a contraction of the head that it will be twisted violently to one side and rotated to an extreme limit. A slight pressure of the hand steadying the head will ordinarily correct it, but where the muscular contraction becomes excessive, great force is required to hold it in place. Often there are occasional contractions which are at first partially under the control of the will, but increase in frequency and severity until they cannot be controlled either by voluntary effort or by mechanical force. The annoyance and pain dependent on this spasmodic condition may be so great as to unfit the patient for work and to impair his health to an alarming degree. The motion is one either of rotation, or of rotation combined with depression of the head towards the affected side, and elevation of the shoulder. The rate of contraction varies from occasional contractions to an almost constant one,—in one case eleven in fifteen seconds.

No true picture of the spasmodic variety can be drawn which can in any way be applied to all these cases. The affection may consist of an occasional twitching of the muscles, coming on frequently for some days and then disappearing for several weeks or months. Again, the condition may begin as in the above, and increase gradually or rapidly until the spasm is nearly constant. A clonic contraction may at times become tonic for a while, and this spasm in time change to clonic again; but even in very severe cases there may be complete remission for days or weeks, although this is not common in this class of cases. This form is rare under thirty, and more frequently is found in women.

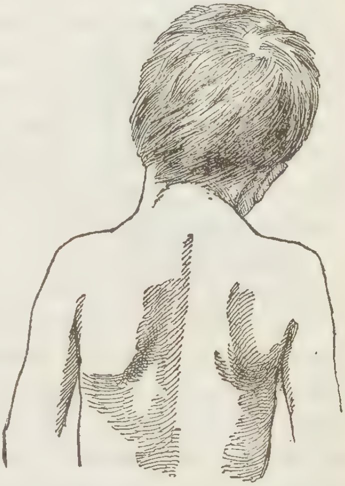
DIAGNOSIS.

There is no difficulty in recognizing the deformity called wry-neck, but the determination of its cause and of the parts involved frequently requires considerable skill. The diagnosis of the muscles affected must be based on an inspection of the position of the head and on palpation.

It is of the greatest importance to distinguish this deformity from other affections which give rise to malpositions of the head resembling it. Such are cervical caries, enlarged cervical glands, deep cervical abscess, and ordinary stiff neck from cold.

For the diagnosis of torticollis from caries of the spine the reader is referred to the article on the latter disease; but the following points may be mentioned. In caries the head is, as a rule, held more rigidly, and there is greater stiffness of the muscles in attempting to twist it. Ordinarily in torticollis there is no pain nor difficulty when the patient lies down, while in caries (Fig. 4) in the acute stages the patient usually steadies the head with the hand when any motion is required, and there is more pain in the back of the head and shoulders. The facial expression is often suggestive.

FIG. 4.



Position in torticollis from caries.

In distortion arising from enlarged glands or from abscess the diagnosis must depend on the recognition of their presence.

A diagnosis between posterior muscular torticollis and torticollis due to cervical arthritis is in some cases impossible. In general, however, it may be stated that there is less evidence of contraction of individual muscles or of groups of muscles in the former. The latter is a rare affection.

The recognition of spasmodic intermittent torticollis is, of course, not difficult, but the diagnosis sometimes involves a consideration of the causes which will produce a deterioration of general nervous strength.

PROGNOSIS.

Acute muscular torticollis ordinarily corrects itself, though in a few cases it may become chronic. Torticollis due to abscess of cervical glands terminates with the complete discharge of the abscess, as a rule. Intermittent spasmodic torticollis may cease spontaneously, or may, as is more common, remain without change for many years. Congenital forms of torticollis, and the acquired form due to muscular contraction which has become chronic and developed fibrous muscular degeneration, are, of course, incurable without surgical interference. Little or no constitutional disturbance follows this affection, which is more distressing on account of the unsightliness than from any actual discomfort. The deaths that are reported as following torticollis have been in a few instances due to septicæmia following operation.

TREATMENT.

The treatment will vary greatly with individual cases, and it is always necessary to bear in mind the cause of the affection to insure any probability of success.

In acute torticollis due to inflammation of the muscles the treatment is largely directed to the alleviation of the symptoms. This is best done by the application of moist heat in the form of cataplasms or poultices and by rest. Oleate of atropine, oleate of morphine, or morphine subcutaneously may be used if necessary. More than this is rarely required.

In all cases the general health should be inquired into, as well as any particular kind of work which would bring excessive use to one set of muscles. In many cases arising from a deficiency of nervous tone, no other treatment than that directed to restoring the health, combined with rest, will be necessary. Such are usually found in overworked adults.

Treatment of cases resulting from caries, from enlarged glands, and from cervical abscess will not be considered, the recognition of the cause being sufficient indication for the line of treatment.

Galvanism to the affected muscles is apparently of benefit in some cases, but these are almost without exception of the spasmodic form, and in patients whose system has been overtaxed, and in whom attention to the general health is fully of as great importance as the local treatment. Some writers deny the advantage of electricity in any case, but the statement is too strong to be fair. In a few cases which were apparently due to faulty antagonism, faradization of the muscles of the opposite side has resulted in a cure.

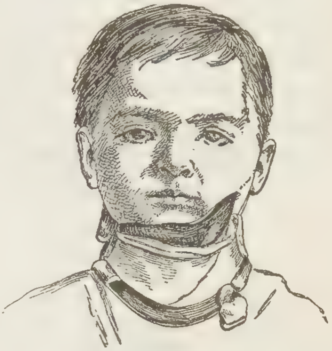
The treatment of the spasmodic and that of the tonic form differ essentially. For treatment the latter variety is to be divided into two classes,—anterior and posterior torticollis,—the first including those cases in which the sterno-mastoid is the muscle chiefly affected, the second those in which this muscle is involved but slightly or not at all.

The treatment of anterior torticollis is either purely mechanical or both operative and mechanical. Mechanical treatment without the aid of operation is ordinarily unsuccessful, but in a few light cases correction is possible by slight supports which relieve the muscles from the strain of the weight of the head. After complete correction some form of retention appliance is needed for some time, for the purpose of habituating the unaffected muscles to their new functions, and for preventing the patient from assuming the position which has become natural.

The only efficacious treatment of posterior torticollis is that of forcible correction without tenotomy, for the reason that the muscles are too deep or too extensive to be tenotomized. In correcting the deformity the patient should be thoroughly anæsthetized, and an assistant should firmly hold the shoulders, the head of the patient projecting beyond the edge of the table, where it can be grasped by the hand of the surgeon and rotated in all directions. The danger of fracturing the spine is slight, and considerable force can be used. Frequently there are superficial bands of contracted fascia; these may be divided by the tenotome, and all such bands and adhesions as cannot be divided should be stretched by manual force. After the head has been over-corrected and fixed in an over-corrected position, a retaining appliance should be used. For this purpose a plaster-of-Paris or a silicate-of-potassium bandage may be employed.

For the correction by mechanical means, or retention after correction, the following devices are useful. All have the principle of obtaining a point of fixation on the trunk from which counter-pressure is made on the head, usually on the mastoid or the parietal region or on the jaw, or else by a circular bandage.

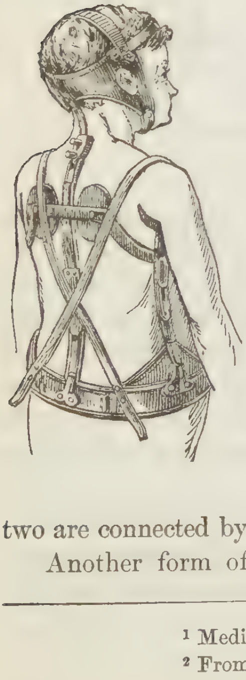
FIG. 5.



The appliance of Buckminster Brown is simple and effective. It consists of a wire collar which has in front a plate so placed as to press the chin to the middle line. Another plate is attached posteriorly, so as to exert pressure behind the ear on the side towards which the head inclines. To the side of the collar is fastened a ring which rests on the shoulder. Behind is an upright, furnished with straps, one of which passes round the body, and one over the shoulder on the side of the deflected chin, and by tightening this pressure is made on the chin and head. This principle is illustrated in Fig. 5, in which the pressure made is the same, but a steel frame is substituted for a wire collar.

A simple means is by adhesive plaster and the ordinary roller bandage. Apply a long strip of adhesive plaster around the forehead and occiput, and make it secure by a bandage round the head, over the vertex and under the chin, pinning these together where the one passes over the other above the ears. Another band of adhesive plaster is carried round the waist, and over this a roller bandage. A ribbon is then fastened to the head-bandage directly above the ear of the unaffected side, and carried diagonally across the trunk to the other side and secured to the waist-bandage.

FIG. 6.



A similar form of appliance has recently been described by Levrat,[1] in which silicate-of-potassium bandages are wound round the head, one horizontally over the forehead and one vertically under the chin, and at the point of intersection above the ear a bent wire is secured to the bandage. Another bandage is then placed round the body, and the two are connected by a strap.

Another form of appliance (Fig. 6)[2] consists of a padded metal plate secured to the back by straps beneath the axilla and around the chest upon the shoulder of the side to which the head inclines. From this plate a rod extends up along the side of the neck to the parietal region, with a padded plate adjusted to this part. The lower end is attached by a ratchet and endless screw, by means of which pressure is made upon the head.

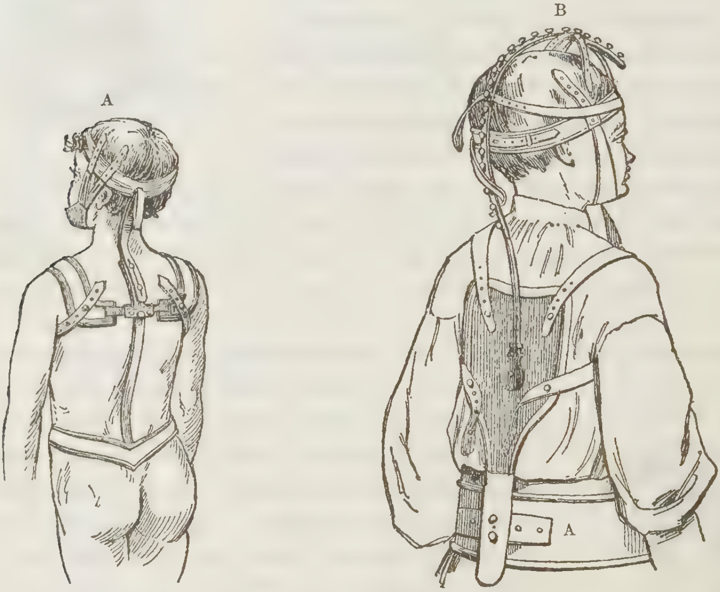
---

[1] Medical Record, February 2, 1889.

[2] From Dictionnaire de Médecine et de Chirurgie, 35.

Several complicated appliances have been devised which in principle are similar to the one just described, and which have for their object the forcing of the head into its normal position. The head is held firmly by large plates or by a helmet, which is connected with a complicated trunk-piece by leverage. (Fig. 7, A and B.)[1] They are all ingenious in principle, but too elaborate and complicated to be practical.

Fig. 7.



A simple form, useful for mild degrees of distortion or for retention after operation, is shown in Figs. 8 and 9. Support is obtained by two uprights, one extending along the side of the spine, continued over the shoulders, joined in front over the chest, and secured by straps passing round the body. To these is fastened, by means of stout wires soldered at the point over the shoulder, a metal or hard rubber plate, which is so applied to the side of the jaw as to keep the face in the median line, while another plate is made to give support to the mastoid and the surface immediately above.

Operative Measures.—Division of the contracted tissues may be done either by subcutaneous tenotomy or by open incision. The advantages of the tenotome are two,—less danger of suppuration, and a smaller scar; but thorough cutting is difficult, and the danger of wounding important vessels in the neck is considerable.

---

[1] From Dictionnaire de Médecine et de Chirurgie, 35.

Open incision, on the other hand, allows more bold and intelligent use of the knife, but the disfigurement is much greater, although with adherence to asepsis one may be reasonably sure of union by first intention.

FIG. 8.

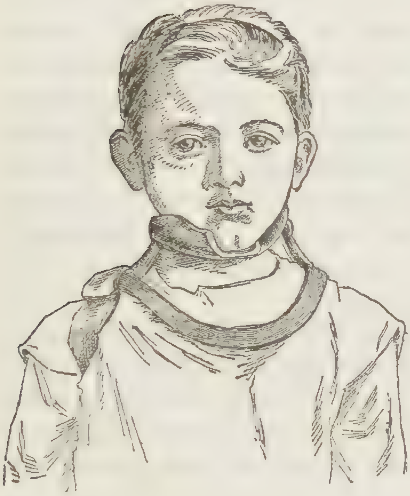


FIG. 9.

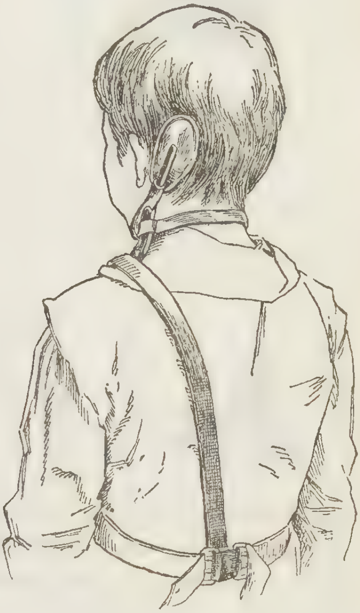


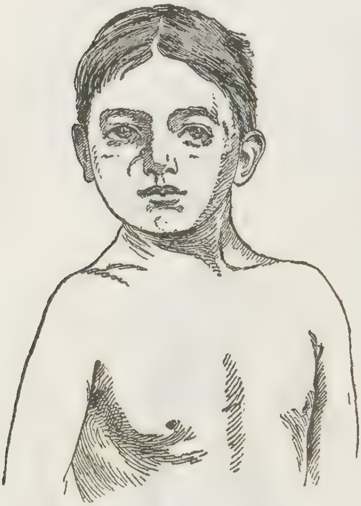
The division should include tendons of both portions of the sterno-cleido-mastoid, if necessary, and any bands of fascia which prevent the return of the head to its normal position. If subcutaneous tenotomy of the mastoid is to be done, the puncture should be made between the two tendons, close to their insertion. A director can then be passed beneath the sternal attachment until the point is felt projecting beneath the skin on the margin of the muscle. This can be divided with a blunt tenotome, and by a careful sawing motion the tendon is felt to give way. Some surgeons pass the tenotome under the skin and cut downward; others pass it beneath the skin and cut upward. The danger of the latter proceeding is incomplete division; that of the former is division of the deep vessels. The superficial veins are to be avoided by careful inspection before the introduction of the tenotome. The clavicular origin can be divided in the same way, passing the director from within outward. The operation is not devoid of danger: Mr. Erichsen mentions three fatal results.

Dieffenbach operates on the left side in the way just described. On the right he inserts the knife between the trachea and the anterior portion of the muscle, and divides first the anterior portion, then the posterior.

If open incision is undertaken, the ordinary precautions of aseptic surgery should be observed. An incision parallel with the clavicle and an inch above it, reaching across the contracted muscle, should be made, a director passed under the muscles and fascia, and the whole divided with care.

After division of the contracted tissues the head should be kept in a corrected or an over-corrected position, either by a plaster bandage or by some mechanical means, until union of the divided structures has taken place.

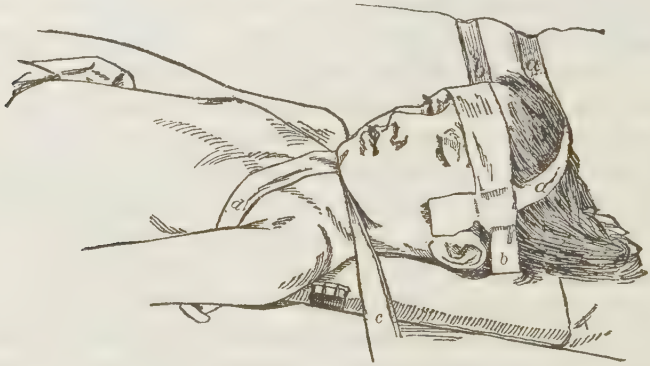
Fig. 10.



The accompanying illustrations are of a case treated by open incision, followed by extension in bed, and later by the use of an appliance. (Fig. 10.) In this case the head was drawn towards the left shoulder, and the chin elevated and turned to the right. After operation the child was kept in bed, and, as soon as the condition of the wound would allow, continuous extension by means of weights was made. The arrangement of the straps for this purpose is shown in Fig. 11.

A piece of adhesive plaster was applied to the right side of the face just in front of and above the ear, and to this was attached webbing, *c*, which passed under the chin to the left side. For the correction of the rotation of the face, a strap, *b*, was carried beneath the occiput and secured to the forehead with adhesive plaster, while another, *a*, was passed over the vertex and secured to the side of the face in the same manner. To the end of each strap a weight was attached.

Fig. 11.



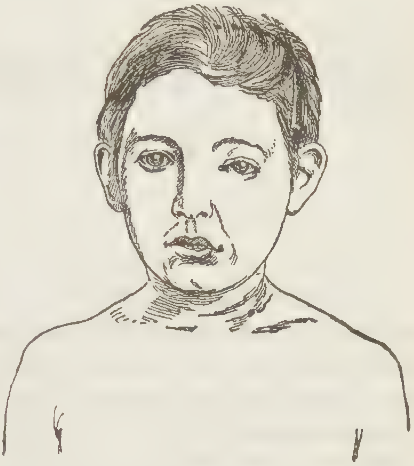
After two weeks of extension, the apparatus shown in Figs. 8 and 9 was applied.

The result is shown in Fig. 12.

In severe cases of *spasmodic* torticollis neurotomy or neurectomy often becomes necessary. Tenotomy, with the rest which follows, affords relief in a certain number of cases, but in cases unrelieved by these means the condition of the patient becomes so serious that extreme measures are justifiable, this treatment being directed against the nerve.

Three courses are open,—nerve-stretching, nerve-division, and nerve-resection. Nerve-stretching has been done a few times, but the results are not encouraging. Probably in cases of this sort requiring surgical interference there is profound central disturbance, which requires complete paralysis of the nerve to put an end to the irritative condition.

FIG. 12.



The situation for reaching the spinal accessory nerve is along the anterior border of the sterno-mastoid. The nerve enters the muscle obliquely about an inch and a half below the mastoid process, and can be found by an incision in this situation. An aid in finding it (Richardson) is to scratch with a director the tissues at the bottom of the wound as the dissection is made, by which the nerve is irritated into causing a contraction of the muscle.

Annandale operated through an incision three inches long commencing at the lower border of the mastoid process and extending along the anterior border of the muscle. Southam exposed the nerve in the posterior triangle by an incision two inches in length along the posterior border of the sterno-mastoid muscle, with the centre on a level with the upper border of the thyroid cartilage. Beneath the fascia the nerve was found running obliquely downward and outward to terminate in the trapezius. This operation was for nerve-stretching; but some operators have advised this site for first finding the nerve.

ACUTE INFLAMMATION OF BONE.

By WILLIAM MACEWEN, M.D.

Healthy bone, in children as in adults, is itself an insensitive structure, whose function is in the main purely mechanical. Its formative stage, the deposit of calcareous salts in the matrix, fibrous or cartilaginous according to situation, is in progress in one portion or another of the skeleton, from its commencement in the clavicle at about the end of the first month of fœtal life, until adult age is fully entered upon, and the epiphyses and diaphyses are thoroughly consolidated with one another. The precise period of this completion varies in different individuals.

The process of inflammation in bone is similar to that in the soft tissues, being modified, however, by the peculiarities of the structure. In bone the vessels of the abundantly-cellular medulla and those of the Haversian canals and the periosteum play the chief part in inflammation. When inflammatory action originates in any part of a bone, all the other parts participate in the action, and, though the terms periostitis, osteitis, and endosteitis are used to denote the part where the inflammation is chiefly located, it must be understood that the contiguous structures are likewise involved, though to a less degree. Further, inflammation originating in one part may induce destruction in other parts, as in the case of periostitis inducing necrosis. Bones which ossify in membrane are by no means so liable to acute inflammatory diseases as those which ossify in cartilage. In childhood the bones are far more vascular than they are at a later period of life, and especially so at their epiphysial extremities, where the active processes of osseous formation are taking place. It is during this most active developmental period that bones are most apt to become affected with acute osteitis and with the slower invasions of tubercular disease, and these diseases attack most often the growing extremities of the diaphyses, the tubercular disease attacking also the epiphyses.

Acute inflammatory action commonly arises in the diaphysial extremities of the long bones in childhood. The osseous tissue is here in process of active development, the cancellated tissue abounding in blood-vessels: hence when inflammation occurs it quickly involves the surrounding soft bony tissue along with the medulla. The inflammatory products thus formed do not spread into the epiphyses, as the epiphysial disk of cartilage prevents that, and owing to the manner in which the periosteum is attached to this disk of cartilage the inflammatory products are guided into the subperiosteal areolar tissue. When inflammation once involves this tissue, it spreads with great rapidity over the whole shaft, stripping the periosteum from the bone. It does so the more readily as there exists a minute interval between the periosteum and the bone, filled with loose connective tissue, along which inflammation travels with great rapidity, as it does in somewhat similar structures, such as the areolar tissue of the pelvis in pelvic cellulitis. Occasionally, especially when the inflammation in the bone is less acute, the periosteum may become soldered to the bone for some distance round the epiphysial lines, in such a manner as to shut off the periosteal areolar tissue and to protect it from the invasion of the purulent extension issuing from the diaphysial side of the epiphysial cartilage. The inflammatory products in such cases escape by ulcerating directly through the periosteum opposite to the epiphysial line. This is somewhat similar to what takes place in serous cavities such as the pleura, where an inflammatory action in the lungs occasionally sets up adhesions between the visceral and parietal layers, when, should there be a cavity in the lungs containing pus, the latter would not be apt to occasion empyema, though the pus might make an exit externally directly through the chest-walls. The neighboring articulations are seldom involved primarily in acute periostitis, as the attachment of the periosteum to the epiphysial cartilage prevents this. The epiphysis, receiving its blood-supply independently of the periosteum, continues to live and grow. The diaphysis, deprived of its periosteal blood-supply, may become necrosed, though necrosis does not necessarily follow. Inflammation may, however, attack the centre of epiphysial ossification during infancy, before the epiphysial disk of cartilage has been formed. When this occurs, the neighboring joint is apt to become involved, this portion of bone being covered with synovial membrane.

Abscess in Bone.—Occasionally the pus formed at one of the diaphysial extremities of a bone remains pent up in the medulla and in the cancellated tissue of the shaft, forming an abscess in the bone. The pus may be strictly localized, or the whole medullary cavity may become converted into an abscess. It often remains for years pent up in the interior, a thick pyogenic membrane forming a lining to it. The bone externally becomes greatly thickened and frequently sclerosed. Abscess in bone is more apt to form in chronic or subacute inflammation, though there are cases where the abscess-formation is ushered in by quite acute symptoms, oftentimes attributed to some general constitutional disturbance, and only long after explained by the finding of the abscess on drilling the canal.

Acute periostitis does not always originate in the diaphysial extremity of a long bone. The inflammatory action may occur initially in the periosteum, in which case the diaphysial extremities of the long bones are not involved at the beginning of the attack, though they may subsequently become so.

Acute periostitis is by no means uncommon in early life, being most frequently seen before puberty, but occasionally occurring during adolescence and even later. It is often accompanied by osteo-myelitis, though it may be impossible to differentiate the latter at the outset of the attack.

Causation.—Its exciting cause is a blow or knock, often so trivial as to leave but a faint impression on the patient's mind, and so slight that it could scarcely cause an appreciable physical detriment to a healthy person. The predisposing cause is a lowered state of vitality, the patients usually being weak, pallid, poorly nourished, and living in bad hygienic conditions. The exanthemata occasionally are followed by acute periostitis leading to necrosis, but the inflammation thus induced partakes more frequently of a chronic or subacute character, and it is often localized, not involving the whole shaft of the long bones. The convalescence from enteric fever is often interrupted by periostitic formations, leading to necrosis. It also happens that acute osteitis and periostitis are more prevalent during or immediately following epidemics of the exanthemata, especially enteric fever, scarlet fever, and measles. Probably these affections, by reducing the patients' strength, render them more susceptible to the immediate cause of the periostitis.

Cases of acute periostitis have frequently presented themselves to the writer in groups of three, four, or five, occurring within a fortnight of one another, raising the suggestion of germ etiology, which is strengthened by the whole course of this acute affection and by its rapid constitutional involvement, and further supported by the demonstration of micro-organisms in the shape of staphylococci and streptococci in the pus removed from the bones and from under the periosteum. The early history of these cases shows that there is an interval of days between the slight injury and the onset of the acute symptoms, sufficient to enable germs already in the circulation to be poured into the damaged tissue, in the blood-clot of which they find a nidus, abundance of food for their development and proliferation, and numerous blood-channels through which the reinvigorated germs may find ingress to the circulation and become scattered broadcast throughout the body. Such attacks are often ushered in by symptoms which have led the parents and medical advisers to the opinion that they were dealing with one of the exanthemata, and occasionally such patients are admitted to the fever hospital certified as cases of measles.

Symptoms.—The attack is frequently preceded by headache and ushered in by vomiting, rigors, drowsiness passing into delirium, and high fever, ranging from 103° to 106° F. These follow one another so rapidly that in both children and adolescents the delirium may supervene within a few hours of the rigor. Other toxic symptoms may appear, such as anomalous rashes of a dull, diffuse, measly type, most marked on the extremities and trunk, though occasionally seen on the face, which is, however, free from indications of coryza. There is low muttering delirium, alternating with screeching-fits induced by pain in the affected bone and periosteum, or by secondary involvement of the joints, kidneys, pleuræ, or pericardium.

During all this time the patient, especially if a young child, may not have referred or directed particular attention to the seat of the disease, and if this be not done at the outset it is often masked by the subsequent involvement of other parts and the clouded mental condition of the patient. In some cases the delirium and the screeching-fits have been erroneously attributed to meningitis, and in others to excessive irascibility. That mistakes may be made in overlooking acute periostitis cannot be wondered at when one knows that the local phenomena are not so obtrusively prominent at an early stage as to arrest attention unless specially looked for. Descriptions of the local appearances are generally given by hospital surgeons under whose notice such cases come at a late period of the disease, when the manifestations of its presence are pronounced, while at an early period the symptoms must be searched for.

When one recollects that the whole process occurs under a dense membrane, little swelling of the limb will be expected. The superficial tissues are not reddened and may not participate in the subperiosteal inflammatory action, though when the affected bone is superficial, such as the tibia, œdema of the superficial soft tissues is the rule.

There is one symptom which is always present in the early stage and which persists throughout the case and may even be elicited when the patient is plunged in a state of low muttering delirium,—that is, pain on pressure over the affected part. Even when the patient is quite unable to answer questions, and is lying in a drowsy, dazed state from toxic influences, firm digital pressure over the affected part will be answered by a sharp expression of pain and often by attempted withdrawal of the limb. In doubtful cases, when the patient is either partially or wholly unconscious, the bones in the body should be carefully and systematically gone over, commencing with the tibiæ, which are most often affected, the femora next, then the bones of the upper extremities, and so on over the body. When firm digital pressure is exerted on the part affected with acute periostitis, the response to the pain produced is immediate,—like placing one's finger on the button connected with an electric bell. When a long bone is affected, pressure upon any part of its diaphysis is generally sufficient to elicit this symptom, yet, if not at once brought out, it is better to run the whole bone over, lest the affection be of limited localization. This is especially needed in conducting examinations at an early period of the disease.

The femur lies so deeply that special care is required in conducting this examination upon it. In one instance an adolescent was sent to the writer's care by the sanitary authorities of Glasgow, to whom the case had been reported as one of fever with an anomalous rash. The patient presented all the general phenomena of acute suppurative periostitis. She was in a state of muttering delirium from which she could not be roused, and therefore she could not give any voluntary guidance as to the locality of the disease. It was only after the most deliberate examination that the painful area was detected at the intertrochanteric line and neck of the left femur. When once found, deep pressure always produced the cry of pain, though pressure over other portions of the shaft did not elicit any complaint. The contour of the two limbs was identical. There was no swelling, redness, nor œdema to be discovered externally on the affected limb. The incision through the soft parts to the bone displayed perfectly healthy tissues until the periosteum was incised, when pus issued and the bone was seen to be bare and probably the seat of osteo-myelitis.

On another occasion a child was admitted into the Glasgow Fever Hospital certified as a case of fever. She had periostitis of the left tibia, and was quite insensible and *in extremis.* So little swelling was there over the tibia that several observers whose attention was directed to it hesitated to pronounce it in any way different from its neighbor. Even when the two limbs were placed side by side the difference, in the writer's opinion, was just perceptible to the eye. Pressure over this bone produced the instantaneous screech, which similar pressure on any other part of the body failed to do. The patient died within a few hours of admission. The periosteum as seen post mortem had lost none of its tenseness. It was stripped from the whole tibial diaphysis by a thin layer of semi-purulent exudation about a thirty-second of an inch in thickness, swarming with staphylococci, large patches of which occupied the field in many places. Organisms of decomposition were of course also present.

Subacute Cases.—In the subacute cases of this disease the progress of the inflammation is slower. The patient retains consciousness and localizes the seat of the affection, the pain causing him to be clamorous for relief. At a late period of the periostitis the swelling of the limb is marked both by periosteal distention and by superimposed œdema. Still later the pus may ulcerate through the periosteum and escape into the soft tissues, when the swelling is increased, the external tissues become reddened, and the limb may even assume the aspect of cellulitis.

In abscess of bone when the acute period is past, dull aching pain is felt, generally with slight increase of temperature, and there is an increase in the size of the bone and also in the sensation of weight the patient experiences.

Necrosis following Acute Inflammation of Bone and Periosteum.—It is sometimes asserted that the underlying shaft when stripped of its periosteum is sure to die. This is erroneous, as necrosis does not necessarily follow. Some surgeons believe that necrosis of the whole diaphysis occurs only when osteo-myelitis accompanies the subperiosteal abscess. Yet this is not wholly correct, for there are cases where total necrosis occurs after acute subperiosteal abscess without osteo-myelitis. In such cases as are being dealt with, diaphysial necrosis occurs in two ways. First, in acute osteo-myelitis, either by the intensity of the osseous inflammatory action causing a rapid proliferation of cells, which fill up the Haversian canals and occlude the vessels contained therein, the stasis of the blood in the latter favoring the occlusion, or by embolism of the minute osseous vessels produced by micro-organisms which swarm in the medulla and spread into all the more vascular parts. Second, by sudden deprivation of blood, asphyxia, occasioned by separation or occlusion of the nutrient vessels and the simultaneous removal of the periosteal blood-supply. Although the bone becomes necrosed in each case, the appearance which it presents varies according to the cause. Where the necrosis occurs from the first cause, the osseous tissue is engorged with vascular elements, it is dark-colored, the medulla being of chocolate hue, and the probe emits a dull note as it strikes against its outer shell. Putridity is prone to ensue, and the odor can be subdued only by removal of the mass of necrosed bone. Ultimately it assumes a dark-yellow color, even when sheathed in the healthy unwounded tissues, and after exposure by an opening rapidly turns black. The necrosis which occurs from the second cause is quite different: the shaft is white, avascular, and emits a clear ring under the probe. There is little if any fetor when first exposed, and when present it is easily removed by free aseptic ablution. The analogy to the moist and dry gangrene of the soft parts is clear.

In dealing with acute periostitis it must ever be borne in mind that the long bones receive blood from both the periosteum and the nutrient vessels, the latter affording the most direct and abundant supply. When the periosteal blood is cut off from the diaphysis and the nutrient arteries remain intact, total necrosis does not occur. Superficial necrosis may do so, in the shape of exfoliations, though in many such cases the vitality of the bone is completely preserved. Total necrosis occurs when from any cause the nutrient vessels become occluded (thrombosis or embolism) or ruptured, and when at the same time the periosteal blood-supply has been removed. In the majority of cases of acute periostitis the nutrient vessels remain intact, and only partial necrosis in the form of exfoliation occurs. In a minority the nutrient vessels are destroyed: this generally occurs at a late stage of the disease, by extension of the inflammatory action causing thrombosis or softening.

It is desirable in any case of acute subperiosteal inflammation to ascertain whether the nutrient vessels remain intact. This may be done in either of two ways. First, at the time of relieving by incision through the periosteum the pent-up inflammatory exudation, the probe, or the finger where possible, may be carefully inserted under the elevated periosteum to the position where the main nutrient vessels enter the bone. If the fold of membrane enclosing the vessels be found intact, it is clear that separation has not occurred, and the probability is in favor of their lumen being patent. Thrombosis, however, may have occurred. Such an examination must be carried out with the greatest gentleness, or the parts which ought to be preserved may thereby be detached. The slower and safer method is to observe the conduct of the denuded bone, which, though when first exposed by the incision made for the relief of the inflammatory exudation it shows an avascular, white, polished surface, yet, when the nutrient vessels are preserved, after the lapse of a few days presents a blush of life, and soon after becomes roseate, the vessels springing from the deeper layers ultimately throwing out granulation-tissue, part of which forms a new periosteum. In the contrary case, where the vessels have become occluded or separated, the bone remains opaque white, gradually changing to a yellowish neutral tint if the purulent secretion is allowed to decompose.

It is fortunate that in the great majority of cases the nutrient vessels are not destroyed, or that, when they are, their destruction is consummated only at a late period of the disease. When their destruction is effected at the outset and synchronously with the complete separation of the periosteum by acute suppurative periostitis, and when both results are sudden and complete, not only does total necrosis occur, but there may also be no bone-reproduction. When the process of the inflammation has been slower and the osteoblasts have been poured out in great numbers from the Haversian canals into the periosteum before the separation of the latter, or when those already existing on the under layer of the periosteum are not subjected to a destructive degree of inflammation, the reproduction of bone is assured, even in total necrosis, the diaphysis becoming buried in a peripheral layer of new bone which grows inward as the necrosed bone becomes absorbed. So that the consequences of this acute periostitis may be divided into three groups: first, where there is no necrosis, or only superficial exfoliation; second, necrosis of the diaphysis, with complete subperiosteal restoration of the shaft; and, third, not only total necrosis, but also destruction of the osteoblasts in the periosteum, and consequent permanent ablation of the bone.

Non-implication of Epiphyses of Joints.—The epiphysis seldom becomes involved in the necrosis, and, when it does, the corresponding joint participates in the suppurative action, which often leads to destruction of the articulation. The inflammation is then very acute. The neighboring joints are often affected with synovitis of a simple kind, which disappears rapidly when the acute inflammation under the periosteum has subsided. Pyæmic involvement of the joints also occurs as a secondary effect, and any of the articulations may be involved. When pyæmia attacks the system, the evidences of it will be looked for in the internal organs. Short of pyæmia, serous effusions frequently occur into the pericardium and pleuræ.

Prognosis.—The prognosis of acute diffuse periostitis and osteo-myelitis is always serious. If permitted to run their course uninterruptedly, these affections are generally fatal from systemic involvement. In forming a prognosis an examination of the internal organs ought to be made for evidences of pyæmia or septicæmia, which, if present, contribute greatly to the gravity of the case. Pericarditis and albuminuria are serious complications.

Regarding the local affection, though the bone be stripped of its periosteum, yet if the nutrient vessels be sound the bone will probably live. If both sources of blood-supply be cut off, the bone will necrose, and when the periosteum and the bone become necrosed there will be no new bone-formation, and a defect in the continuity of the bone will result. When, however, such cases are seen at a very early period and promptly treated, much may be done to avert the more serious consequences both to the life of the patient and to that of the bone. In some such cases the malady has been actively treated by incision at a period when the inflammatory products, though containing pus, were chiefly composed of leucocytes, after which not only did the patient promptly recover, but the localized affection also rapidly disappeared, leaving no subsequent trace of its presence except the linear cicatrices made for its relief. There was not even an appreciable thickening of the bone.

Treatment.—In acute suppurative periostitis free aseptic incisions through the periosteum are to be made *as soon as possible:* first, to remove the pus filled with micro-organisms, and so to prevent septicæmia and pyæmia; secondly, to allow the periosteum to fall into its normal position relatively to the bone, and so to restore its functions; thirdly, to diminish the intense pain suffered. After the free incisions have been made in the long axis of the bone, an antiseptic douche ought to be applied, in order to clear away the whole of the subperiosteal pus, and, if possible, to render the parts aseptic. Delay in freely incising the periosteum, while leeches and fomentations are applied, means disaster. It is better even to err by making the incision too soon than to make it too late. When all the pus has been removed, antiseptic dressings ought to be applied.

As a rule, this proceeding is followed by a rapid reduction in temperature when the case is distinctly local and when there is no osteo-myelitis of a pronounced kind. When the temperature has not been greatly reduced within the first forty-eight hours, inquiry ought to be made regarding the possible involvement of the lungs, heart, and kidneys, and also the joints. If all these are free and the high temperature persists, in the absence of pockets containing pus, there is a probability of osteo-myelitis, which is generally accompanied by a dull aching pain in the bone. When osteo-myelitis is present, the bone ought to be freely drilled, so as to expose the medullary canal and permit the inflammatory products to escape. In order to preserve the epiphysial cartilage and the epiphysis itself from inflammatory invasion, which is apt to occur by extension from the pent-up inflammatory products in the vicinity, the diaphysial extremities ought to be perforated near to, but not involving, the epiphysial lines.

After the relief of the periostitis the exposed bone ought to be carefully protected, and occasionally closely scrutinized, with the object of noting its behavior. As long as there are any signs of vitality it ought to remain undisturbed. Even when appearances indicate the probable death of the bone, this may be only partial and superficial, and while preserved aseptic it is well to allow it to remain until fresh bone be developed in the vicinity of the old. Exfoliation and sequestra may form, and yet there may be a considerable framework of bone left, sufficient to preserve the continuity of the shaft. When it is evident that total necrosis has occurred, it is well to delay removing the shaft for at least several weeks, until a new shell of bone has formed in the periosteum and until there has been a line of granulation-tissue formed between the epiphyses and the shaft, when the shaft may be levered out of its position with the least possible disturbance of the epiphysial extremities.

In those unfortunate cases where the osteoblasts and the bone have perished by the intensity of the inflammation, and no bone-reproduction takes place, after removal of the bone and the products of decomposition it is best to allow the wound to heal, to restore the health of the patient, and subsequently to build up a new bone from fresh osseous grafts. In the mean time there may have been some slight osseous reproduction from the epiphyses, but, as a rule, this is so slight as not to be of practical value. In order to prevent shortening of the limb until the grafting has been completed, extension should be maintained, especially when the femur or the humerus is involved.

LATERAL AND FUNCTIONAL CURVATURES OF THE SPINE.

By V. P. GIBNEY, M.D.

Definition.—A deviation of the spinal column to one or the other side, frequently accompanied with rotation of the bodies of the vertebræ on the vertical axis, is what the profession generally understands by the term lateral curvature of the spine.

The effort made by the patient to maintain a vertical bearing very early converts a single curve into three, giving primary and compensating curves. One seldom, therefore, finds less than a letter S, more or less perfectly formed, as the shape which this deformity assumes.

Functional curvatures represent antero-posterior and lateral deviations, with or without compensating curves. The rotation element in this class is absent. The term functional is in this connection very nearly synonymous with compensatory. The deviation depends upon the interference with function in certain organs, and is remedied when the function is restored.

History.—Spinal curvature was divided by Hippocrates about the year 400 B.C. into *cyphosis*, *lordosis*, and *scoliosis*. Curiously enough, the latter term is the most scientific at the present day. While references may be found in the works of Ambroise Paré, 1650, and in those of Glisson about the same time, nothing of special importance pertaining to this deformity is found in medical or surgical writings until the beginning of the present century.

Rotation of a vertebra was first alluded to by M. Le Clercq in 1710. This reference was in a work entitled "The Compleat Surgeon." In 1824, Andrew Dodds, of London, developed this idea, and gave to lateral curvature the name of rotated or contorted spine. In the same year Rogers Harrison, in a work on "Deformities of the Spine and Chest," wrote as follows: "To conceive the cause of this extraordinary derangement it is necessary to imagine that, in a well-marked curvature of the spinal column continuing to sustain the weight of the body, the vertebræ of the middle of that curvature are, in fact, in the same situation as if they were urged by a direct and horizontal force on the side of the concavity towards that of the convexity. In this impulsion the body of the vertebra, isolated in its anterior and lateral parts, experiences no resistance, but the articular processes are powerfully restrained by their reciprocal connection. The transverse processes find in their articulation with the tuberosities of the ribs a resistance to their deviation, which would be very weak on the part of an isolated rib, but which becomes considerable by its union with the adjoining ribs. It results from this exposition that behind the central part of the dorsal column there is efficacious resistance to its lateral displacement, and, consequently, the vertebra must necessarily turn on its axis to arrive at the position which observation so frequently presents."

In presenting the history of the deformity under consideration, it certainly seems necessary to give space to this theory, and at the same time to refer my readers to the ingenious contrivance of Dr. Judson presented to the Academy of Medicine in 1876. Cuts of this device have been so often reproduced that I take it for granted that all are familiar with its appearance. It consists simply of vertebræ placed in normal position over a flexible rod, of which the lower end is fastened to a board and the upper end passes through a hole in a board parallel to the lower board, pressure on the top of this rod downward giving a deflection of the column to one or the other side, which deflection is combined with rotation.

The most exhaustive treatise on lateral curvature is by Mr. William Adams, of London, the first edition of which was published in 1864. The history of the suspension treatment dates as far back as 1650, when Glisson's work "De Rachitide" was published. Glisson's swing was for many years popular in Germany and England. It is not strange, therefore, that this method should be revived from time to time. To the late J. K. Mitchell, father of one of America's most distinguished physicians, we are indebted for the introduction of the suspension treatment of spinal curvature into this country.

Etiology.—The dorsal region is more frequently the seat of deformity, and the convexity, as a rule, is towards the right. A much smaller proportion of cases present the primary deformity in the lumbar region, and a still smaller proportion in the cervico-dorsal: these are usually to the left. In the *Centralblatt für Chirurgie*, No. 21, 1886, Kölliker, in an analysis of seven hundred and twenty-one cases, found four hundred and sixty-six single curves, three hundred and ninety-one of which were dorsal. Two hundred and eight of this number had the convexity to the right, and one hundred and eighty-three to the left. There were two hundred and twenty-two double curves, one hundred and seventy-two of which presented the convexity to the right in the dorsal region, and to the left in the lumbar. Without making an analysis of the cases that have come under my own observation, I am fully prepared to accept the statistics of Kölliker as reasonably accurate.

Sex seems to be a predisposing cause, as we find the deformity more frequently in girls than in boys, the proportion being about four to one. Ketch, of New York,[1] found one hundred and eighty-nine females to forty males, and Kölliker, of Leipsic, five hundred and seventy-seven females to one hundred and forty-four males.

---

[1] Medical Record, April 24, 1886.

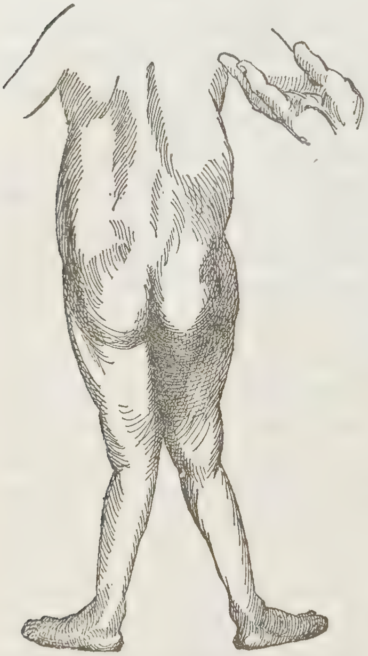
The above statistical references lead naturally to a consideration of predisposing causes. The profession, in this country at least, is indebted to Dr. Ketch for calling attention to the frequency with which curves are seen in infants and young children. The general impression is that curves develop most frequently between the ages of eight or ten and fifteen years. My own experience coincides with this impression, although a certain proportion develop in infancy. The claim is made that mothers and nurses are so defective in their powers of observation that many infantile curves are overlooked. I am not satisfied that this is true. The mother, in my experience in both private and dispensary practice, is, as a rule, quite observant on this point. Occasionally, however, I have asked her how she happened to observe so slight a deviation in a baby, and the answer has been that some relative or intimate friend of the family had such a curve, and in this way her attention had been directed to the subject. It is certainly gratifying to the orthopædic surgeon to find a more general interest, in both the medical and the lay mind, in deformities and joint-diseases. The result is that many cases in their incipiency come under treatment, so that our concern is to prevent, rather than to correct, deformity. Age, therefore, is a predisposing cause.

Congenital asymmetry is regarded by some German authors as a predisposing cause, yet this certainly lacks demonstration. Muscular weakness, which is so common in the wake of certain fevers, is one of the most prominent of the predisposing causes.

So far as my own observation goes, rickets takes the leading place in the way of predisposition. Reasoning *a priori*, one can readily see how important a cause this defect in nutrition may be. There is a lax condition not only in the soft parts, but also in the osseous. The flabbiness of muscles, the laxity of ligaments, the epiphysial enlargement, and the general lack of bony hardness render the child incapable of withstanding the slighter traumatisms of infancy. When one considers the normal symmetry of the spinal column, how accurately the lamina of one vertebra fits upon the lamina of another, and how essential it is to preserve this symmetry during the period of development, it becomes all the more remarkable that lateral curvature is not of more frequent occurrence. It is hardly fair to assume that rickets is more prevalent now than formerly, but it is fair to assume that it is more frequently recognized. The profession in general has become so well informed on this subject that one no longer looks for rickets among the poor alone, but finds it very frequently among the upper walks of life. Any inequality, therefore, in the articular facets of the vertebra will predispose to lateral curvature; this inequality may be induced by position long maintained or by traumatism. A striking analogy may be had in rachitic knock-knee and bow-leg. (See Fig. 1.)

Some writers on this subject attach much importance to an inherited diathesis, as predisposing to the deformity under consideration: I do not believe, however, that diathesis plays any important part. I am quite willing to admit that an acquired diathesis—or, rather, a cachexia produced by long illness or by poor hygiene—does take an important place in the list of predisposing causes. I wish here to make a distinction between hereditary diathesis and heredity. By the former is meant scrofula, or, to use a more modern term, tuberculosis, while by the latter is meant the transmission of a deformity direct. We are all more or less familiar with cases occurring in two or more members of a family while the mother or the father also presents a similar deviation from the normal. I have at present under observation two daughters in one family, one of whom has a marked rotary lateral curvature, the other a slight one, while the mother herself presents a rotary curve in the lumbar region.

Fig. 1.



Rachitic scoliosis in a case of genu valgum.

The exciting causes in the order of their prominence are as follows: *weight*, *static*, *inflammatory*, and *neurotic*. By weight is understood the superincumbent weight of the body acting, by reason of faulty attitude, in a direction not in the line of the vertical axis. Faulty positions in sitting or standing, that become habitual, are among the most frequent conditions producing a curvature. One can readily see how a boy or girl at school may assume these positions quite unconsciously because of impaired health or lack of symmetry in the laminæ or articular facets. Before public attention was so forcibly called to school hygiene, the construction of the benches, chairs, and desks was so faulty that children were often compelled to take awkward positions in order to secure rest. Fortunately, in the more enlightened schools of the present day this necessity seldom exists.

Another cause which may be properly classed under the weight theory is vocation. By this is meant the more constant use of one side of the body, supplemented by the employment of a greater or less amount of strength. This, of course, develops the muscles of one side to excess, and curvature becomes quite easy of production, especially when the predisposing cause exists. After ossification is complete, these vocation scolioses are less apt to occur: hence the importance of a full knowledge of the danger of requiring of children any prolonged occupation. (Fig. 2.)

By static is understood a cause which depends upon unequal length of

PHOTO. 1.

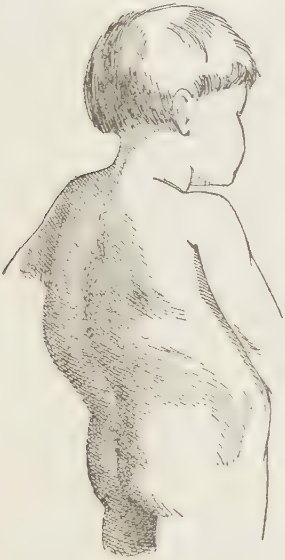
SHOWING SCOLIOSIS CORRECTED BY EQUALIZING THE PELVIS.

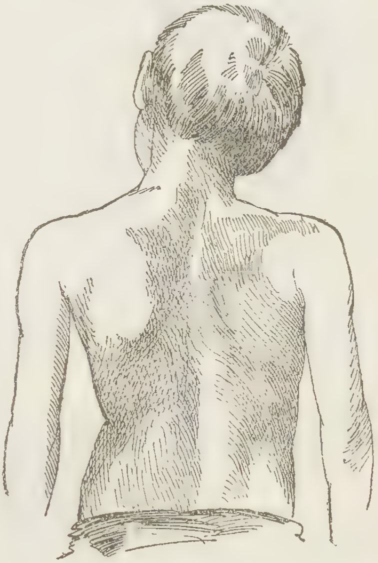
the lower extremities, or upon unequal functional power. Photos. 1 and 2 are from photographs of a patient now under treatment for disease of the hip, third stage, with shortening. Photo. 1 shows the deformity as she attempts to place both feet on the floor. Photo. 2 shows the deformity of the spine corrected by bearing her weight on the left—the sound—limb. (The bandage on the right limb was applied for the retention of adhesive plaster, and is nothing pathological.) The pelvis itself may be oblique, and hence the column above it is deflected even where the limbs are of equal length, so that there is practically a crural asymmetry. Some writers describe a curvature dependent upon this cause as incidental. In affections of the hip where the function of the joint is for a long time impaired, we sometimes find a curvature which is known as static.

FIG. 2.



Rachitic scoliosis to the left, with cyphosis.

FIG. 3.



A case of torticollis showing cervico-dorsal scoliosis.

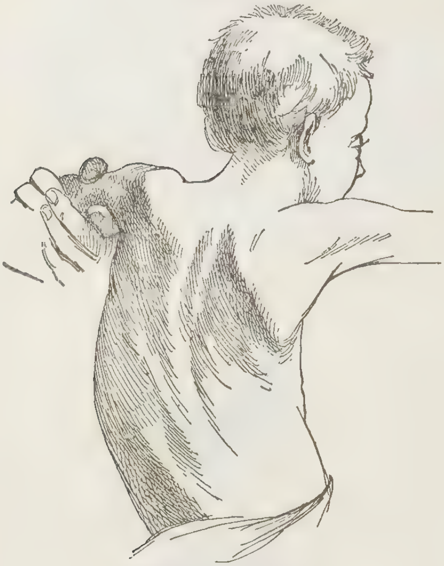
Albert and Nicoladini have described cases of scoliosis that depend upon sciatica, and we can readily understand how prolonged impairment of the function of a limb thus affected could produce a lumbar deviation.

Among the inflammatory causes we have torticollis, cicatrices, and pleuritic affections, notably empyema. In recording wry-neck as an inflammatory condition, I desire to explain, as follows. Congenital torticollis is due, as a rule, to a hæmatoma of the sterno-cleido-mastoid, and about this blood-tumor inflammatory changes take place, resulting in shortening of the muscle. (Fig. 3.) In acquired torticollis, malaria and rheumatism figure most prominently. I am quite willing to admit that the torticollis which results from malarial poisoning is neurotic in character. Authorities differ somewhat as to the locality of the lesion,—as to whether it is in the nerve or in the muscle. A mild grade of myositis is often recognized in rheumatism. Rheumatism most commonly invades the fibrous structures, and rheumatic torticollis is usually regarded as a cervical periarthritis, directly implicating the nerves in their course to the different groups of muscles.

With the deformity which results from empyema we are all more or less familiar. A curvature results by reason of impairment of function of one side of the chest, with corresponding increase of function of the other. (Fig. 4.)

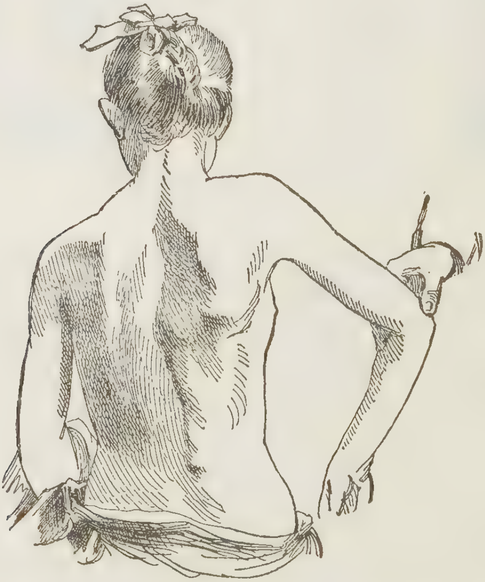
The deformity in empyema is a pure lateral curve, with very little of the rotary element. Not only is the chest-wall expanded on the convex side, but the column itself is also drawn in this direction. The curve is generally easy of correction, and the usual form of brace is well adapted to an empyemic lateral curvature.

Fig. 4.



Scoliosis from empyema.

Fig. 5.



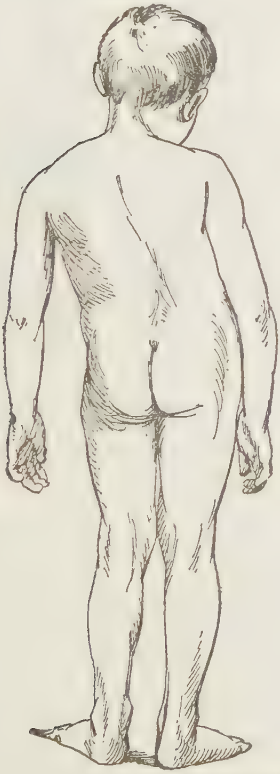
A scoliosis dependent on myositis ossificans. The right arm is raised from the side to the full limit, the resistance being due to ossification of the tendon of the latissimus dorsi.

In certain forms of rheumatism—the arthritis deformans, for instance—the curve sometimes occurs as a result of muscular shortening or spasm.

I distinctly remember a curvature which developed as a result of myositis ossificans in a case that I presented to the Pathological Society many years ago. (Fig. 5.) Among the inflammatory lesions which produce scoliosis may be mentioned cicatrices from burns, lacerated wounds, and old sinuses.

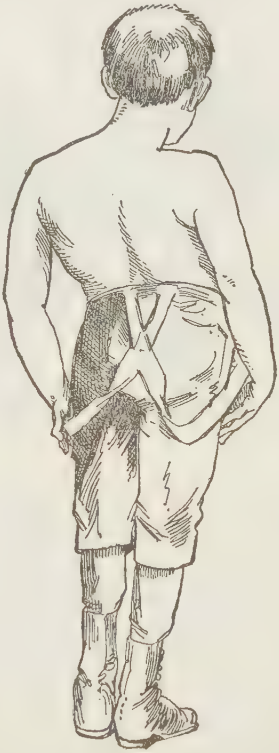
The neurotic curve is not an infrequent one, and may be either akinetic or hyperkinetic. In the former we have loss of power in the muscles, and ordinary stimulants do not have any effect. In this instance the equilibrium is not maintained, and the opposing muscles, of course, act without the necessary restraint, and a curvature results. (Fig. 6.) Polio-myelitis is the most common form of paralysis which belongs to the infantile period. The curve dependent upon paralysis is usually lumbar, for the reason that the groups most commonly affected are those having their attachments to the spinal column and one or the other of the lower limbs. Where the shoulder group of muscles are involved, the curvature is naturally dorsal or cervicodorsal. (Figs. 7 and 8.) I have at present under observation a case of paralysis of the transversalis and oblique (external and internal) caused by

FIG. 6.



High dorsal scoliosis from infantile cerebral hemiplegia.

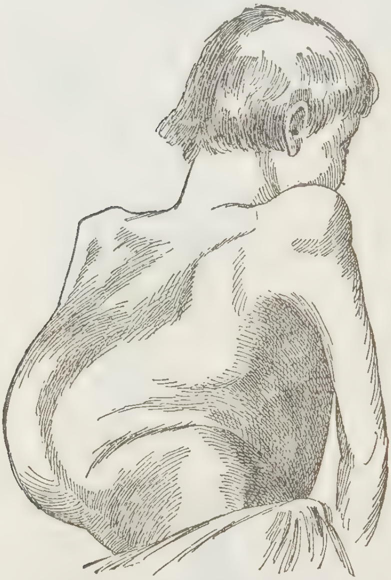
FIG. 7.



High dorsal scoliosis to the left, dependent upon paralysis resulting from polio-myelitis.

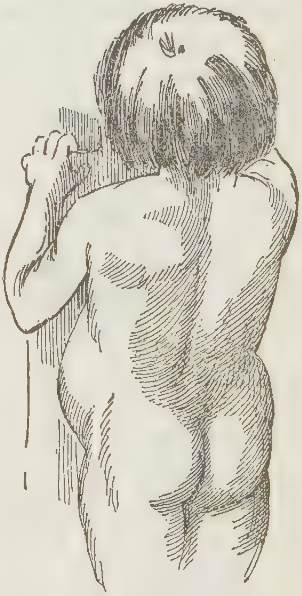
a polio-myelitis seen eighteen months ago, and the case is a lordosis confined to the lumbar region. By reason of the lack of symmetry, the paralysis of the muscles on the right side being more extensive than that of the muscles on the left, the scoliotic curve was towards the left side. (Fig 9.)

FIG. 8.



High degree of scoliosis, with cyphosis, the result of paralysis from polio-myelitis.

FIG. 9.



Lordosis with slight scoliosis in a case of paralysis of the transversalis and oblique, resulting from polio-myelitis.

The lack of muscular power is most beautifully shown when the child cries.

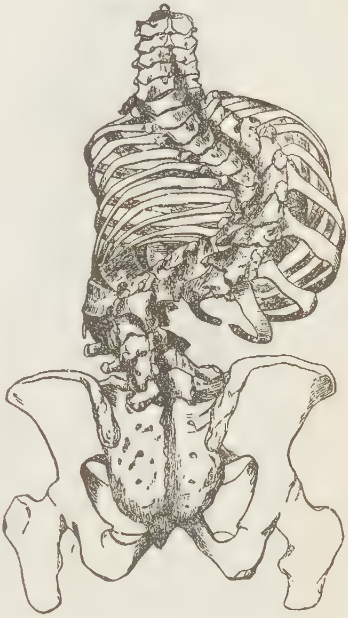
In enumerating the causes, both predisposing and exciting, I may have unwittingly passed over some of minor consideration; but I am sure that all of any practical value have been included.

Pathology.—Naturally, in going so fully into the etiology, much that pertains to the pathology will of necessity be included. The distinction between Pott's disease and lateral curvature is that in the one the osseous changes are due to an osteitis, in the other they are due to mechanical pressure. It is seldom that any inflammatory changes are found in scoliosis. The pain that is often an underlying feature is induced by pressure on nerve-roots or on other sensitive structures. We find in a confirmed case a specimen, which may be described as follows:

General.—A rotation or twisting of the spinal column, producing not only lateral but also antero-posterior curves, a distortion of the head and neck, a prominence of one shoulder, a flattening of the ribs on one side, with an increased curve on the other, an inequality of the thoracic cavities, a shortening of the vertical diameter of the abdominal cavity, with overlapping of the free ribs and the alæ of the pelvis,—besides an alteration in shape of the thoracic and abdominal viscera.

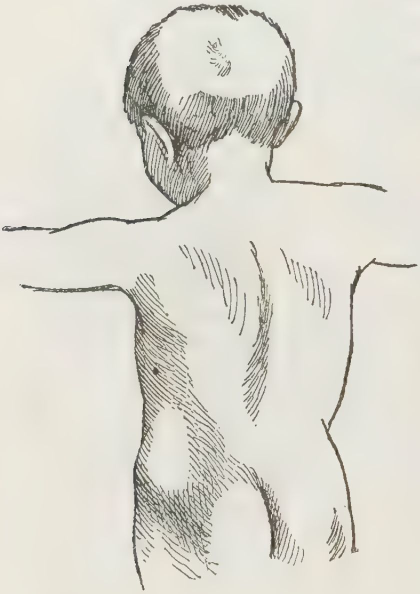
Special.—An amount of transverse rotation of one body on the other, proportionate to the severity of the case and to the locality of the deformity; a wedge-shaped appearance of the bodies of the vertebræ, the base of the wedge being towards the convexity; an alteration in the transverse processes, with a like change in the articular facets, —this is best shown by a diagram I have taken from Mr. Adams. This diagram (Fig. 10) shows a slight deviation of the apices of the spinous processes, and the altered relations of the transverse processes; a posterior projection of the angle of the ribs on the concave, and a recession of this angle on the convex side; and a diminution in the height of the spinal column. Minor appearances, of course, are noted, but, pathologically speaking, the changes above noted comprise the most important features. Some recent writers maintain that an osteitis takes place, and that we have very nearly the same lesion in a lateral curvature that we have in a Pott's disease. Proof is wanting, however, for this, and for the present, at least, in children, no authorities of any note can be quoted in confirmation of this view. It is true that atrophy of bone takes place, and that contact of one transverse process with another, by reason of the twisting and the deviation, may produce a peripheral osteitis, and there may be osseous adhesions here; but these are all secondary to the original lateral curve, and cannot be considered as a pathological process in rotary curvature.

FIG. 10.



Clinical History and Diagnosis.—In the early years of child-life it must be understood that certain signs are present, and that these can be found on close examination. A child should be stripped quite naked, and an observation for symmetry made with the patient standing, sitting, walking, and lying down. One can readily discover any discrepancy that may exist on one or the other side of the body. This discrepancy is usually in the form of a projection of the ribs backward and outward, a slight prominence of the angle of the scapula on one or the other side, and a raising of one shoulder, the child habitually carrying one shoulder higher than the other. (Fig. 11.) These signs can be discovered, I say, quite early, and, while the mother may overlook this, it occurs to me that mothers should be taught this inspection of their children, who must continuously come under their observation while bathing them. A further sign is some irregularity of the sternum, either a "pigeon-breast" or a "bird's nest." The costal cartilages below the ribs may be irregular. These changes in front are suggestive, to say the least, and indicate, as we know, a rachitic cachexia. One will at this period look in vain for any deviation of the spinal column to the right or to the left: this is a later sign. Comparative measurements of the two sides of the chest will reveal an inequality,—slight, but still present.

Fig. 11.



Early stage of scoliosis in a small child.

More prominent signs are found as the child is older,—in fact, as the child approaches the age of adolescence,—and I am sure I shall be pardoned for giving these signs as they may be found in early life. They are as follows.

There is an apparent obliquity of the pelvis,—a depression of the ilio-costal space on one side, with obliteration or partial obliteration of this space on the other; the free ribs approximate the crest of the ilium; the chest-walls may be apparently a little large, or may form a ridge in a vertical line, instead of presenting the rounded appearance of health; the spinal column itself has the shape of a letter S, more or less exaggerated; the spinous processes are conspicuous in certain regions and hidden in others; the erector spinæ muscles, and other muscles intimately associated with the spinous and transverse processes, show a ridge-like prominence on the side of the convexity. The scapulæ are very uneven, the one on the convex or bulging side projecting forward and backward rather, giving the name of "angel's wing," while the one on the concave side hugs the chest-walls closely, and its lower angle looks forward rather than backward, and approximates the vertical line; the muscles running from the head to the shoulder show prominence on one side, dependent altogether upon the locality of the curve; and the mammæ are unequal in size, the one on the concave side being usually the smaller. (Figs. 12, 13, 14, 15, 16.)

In addition to all this, there may be much pain in the back. In females very often there is a sensitive spine, such as one finds in hysterical subjects. There may also be intercostal neuralgia. If the patient be made to bend forward, with limbs parallel and knees extended, bending chiefly at the waist, the rotation can be distinctly seen. (Fig. 17.) In slight cases a rotation can be observed in this way. At the point of distortion the spinous

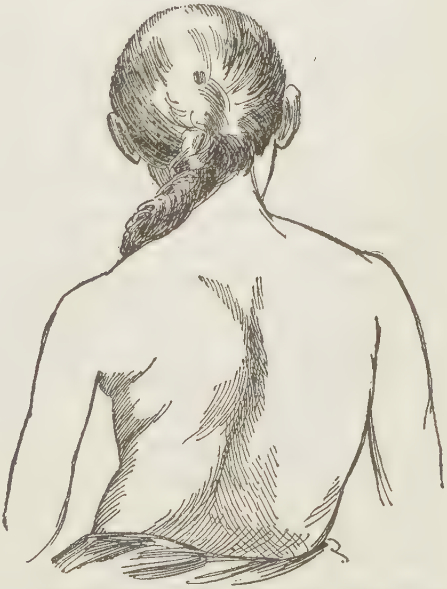
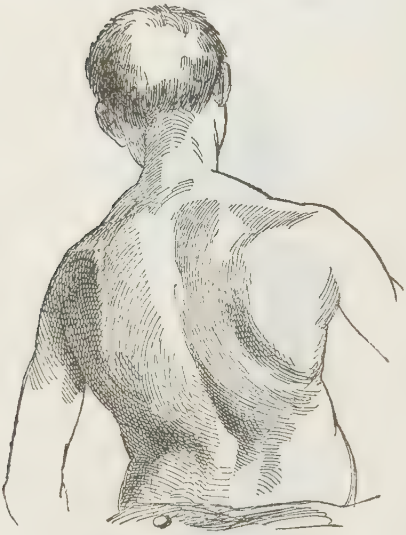
FIG. 15.



The most common form of scoliosis,—dorsal to the right.

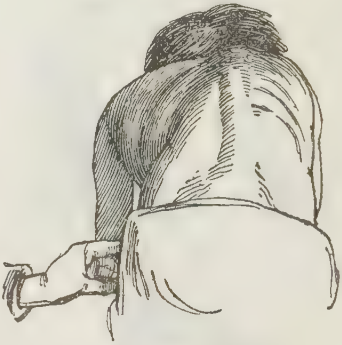
processes can with difficulty be recognized. The meaning of this is obvious. One can readily see how a twist in the bodies of the vertebræ will deflect the tips of the processes to one side, and thus render them inconspicuous.

FIG. 16.



Dorsal scoliosis to the left in a boy.

FIG. 17.



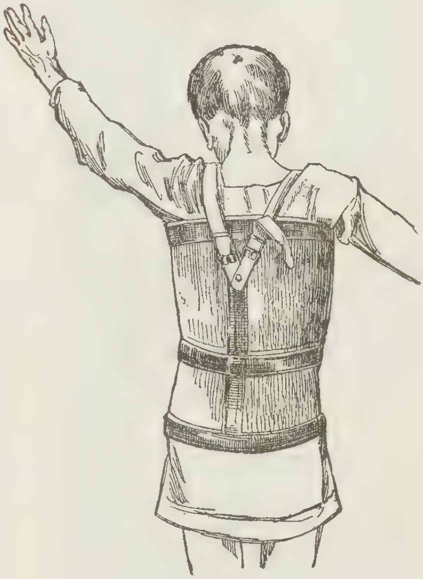
A case of right dorsal scoliosis, the patient bending forward to show the amount of rotation.

Such are the signs and symptoms observed in the case of lateral curvature of the spine. With a knowledge of these facts one can readily make a diagnosis very early in the affection; and, as the science of medicine progresses, the duty of the physician to recognize diseases early, before the stage of deformity comes on, cannot be too strongly emphasized.

Treatment.—In discussing the treatment of curvatures of the spine, regard must be had to the age of the patient, to the intelligence of the parents, and to the stage at which the deformity comes under surgical observation. In very young children—infants, in fact—I do not often find it necessary to apply apparatus. The mother's hands can be made to serve a useful purpose in correcting a slight amount of deformity at this period of life, and, if one instruct her how to press upon the convex side from behind forward, and upon the concave side from before backward, a pretty fair amount of rotation in the opposite direction can thus be induced. This procedure should be repeated several times during the day; and, in the second place, a position should be taught by which the child will get the weight of its head and lower extremities acting against a fulcrum of some kind at the point of greatest deformity. Thus, the mother or nurse can be taught to seesaw the child, as it were, with the hand, when holding it, and when lying down a hard pillow can be placed under its side. In other words, teach the mother the principles of treatment, tell her just what you hope to accomplish thereby, and enlist her fullest co-operation. Her sympathy and her attention you are sure to enlist. If evidences of rickets be present, treat this condition by appropriate remedies, such as cod-liver oil, stomachics, and phosphates. The nutrition of the child, of course, must be improved. If much deformity exists, then a very simple form of apparatus, consisting of a brace made so that pressure will come on the convex side, can be employed.

After using various forms of appliance, I am convinced that the brace known as the Knight brace, used by Dr. James Knight for many years at the Hospital for the Ruptured and Crippled, serves the best purpose. The adjustment of the appliance, of course, is all-important. It should be made of light steel, the bars should fit the body, and all unnecessary upholstering should be omitted. This apparatus is figured here (Fig. 18), and has the advantages of being light, open except where pressure is needed, and inexpensive. If one attempts, however, to fit the child to the brace, rather than the brace to the child, success will surely be wanting.

FIG. 18.



The Knight brace for lateral curvature.

I have had no experience with the Shaffer brace in very young children, but can readily see how this could be so adjusted that the deformity would be corrected. I regret that I am not able to present a cut of this apparatus. It consists of two bars arranged like the blades of a pair of scissors, the joint being placed just over the lumbo-sacral spine. One of the long arms carries a pad or plate which makes pressure over the ribs of the convex side, the other an axillary crutch which is held in position by a strap of webbing passing from the front of the shoulder backward to the pad just mentioned. The handles of the scissors, so to speak, are secured to the pelvis by webbing, which passes from behind around over the front, and a buckle serves to separate the handle, thus increasing the pressure over the projecting ribs.

The Barwell dressing could also be used with advantage in the lateral curvature of infants. My own experience with this dressing is confined to adolescent cases. With the aid of a dress-maker, a well-fitting appliance can be constructed, as shown in Fig. 19. The figures on the following page (Figs. 19–22) I have taken from Mr. Barwell's article on "Lateral Curvature of the Spine," published in the *Lancet* for August 13, 1887, pp. 302 and 303. The two sets of illustrations appear almost identical at first glance, but Figs. 21 and 22 have, Mr. Barwell claims, a very different action, and this bandage is to be employed when rotation is strongly marked.

However useful a plaster-of-Paris corset may be in adults or in adoles-

The Same Patient without Self-Suspension.

cence, one seldom thinks of employing it in very young children. Indeed, the consensus of orthopædic opinion to-day is against the use of the corset, except in cases where gymnastic exercises are impracticable. This remark holds good with respect to all plastic appliances, such as felt, leather, raw-hide, tripolith, etc. In children under eight years of age a jacket is sometimes a necessity,—so many, I find, are hard to manage in a gymnastic class. These children require an extra amount of drilling,—individual drilling,—and home co-operation is seldom available: so that my practice is to put these cases, as a rule, in either a plaster-of-Paris corset or a steel brace, described above.

I have introduced Photos. 3 and 4 in order to show just what can be accomplished by self-suspension, and the query would naturally arise in the mind of the reader, why not employ this method of treatment? The reply is that the improved position can be retained very easily in the plaster-of-Paris corset, but as soon as the corset is removed the deformity recurs, and in an exaggerated form, because the muscles are weakened more or less by the use of the jacket; and it so happens that this special case did fail to improve, and the deformity became more marked while she was under this plan of treatment.

Much can be done by instructing the parents in the kind of chairs to use at home, or a special chair for the child can be constructed, with one side a little higher than the other, so as to force the child to sit in a position that will correct the deformity. Often an inequality in the lower limbs, not appreciable by measurement, can be corrected by raising the sole of the shoe, or even the heel. One is so prone to measure the limbs with a tape-measure, and then say there is no occasion for a high shoe, because he finds no actual difference; but the pelvis is very often tilted, and by raising the limb in the vertical axis the pelvis is placed in a horizontal plane, and the deformity is corrected. Sometimes by raising the pelvis still higher the same result is attained. All these means can be employed with great advantage.

The treatment by medical gymnastics is gaining ground, and is certainly worthy of commendation. We are indebted to Sweden for the development of this method of treatment, and no city is without a number of professors in so-called *mécano-thérapie.* For two or three years I have, in general, adopted the formulæ of Mr. Bernard Roth, of London, but have modified my exercises in accordance with what seemed to be the indications of the case. I find it necessary, as he states, to superintend this treatment, and the necessity for drilling is just as important here as in any other study. As a matter of routine I generally prescribe the following exercises.

1. *Respiratory.*—This consists in taking a deep breath, holding the breath as long as possible, and then gradually exhaling. The inhalation is made with the mouth closed, the exhalation with the mouth open. The shoulders must be thrown well back, the palms of the hands looking forward, and the body as nearly erect as possible. It is needless to say that all tight clothing about the neck must be removed. From three to five deep

breaths in succession are taken, the patient standing. This exercise is repeated with the arms extended above the head, shoulders thrown back, palms forward, the same number of times.

2. *Head Rotation.*—With the shoulders thrown well back, arms by the side, and palms looking forward, the patient rotates the head from side to side to the fullest extent, and at the same time employs as much force in the act as possible. Twenty times for this movement.

3. *Lateral Flexion of Head.*—Same position as in above, with head flexed from side to side without raising the shoulders. Twenty times for this movement.

4. *Circumduction of Arms.*—As complete circumduction as possible, shoulders well thrown back, forearms extended. From ten to twenty times.

5. *Leg and Thigh Circumduction.*—This is a circumduction of the right lower limb, leg fully extended, motion at the hip, the patient lying prone on a hard table, pelvis near the end. Five or six rotations each way, right and left. Then have the patient lie on the back and execute the same movement five or six times each way.

6. "*Pugilistic.*"—This is a name I have given the exercise which is described as follows. The patient stands erect, shoulders well thrown back, forearms extended on arms and the whole limb extended forward at a right angle with the body, palm of hand looking upward ; clinch fist, flex forearm vigorously on arm, which falls to the side of the body, extend again in first position, flex again as before, extend arm from the side with forearm fully extended, bring arm and forearm down to the side of the body, palm still looking forward. Let the patient count five for this movement, and execute the whole exercise from seven to ten times.

7. *Thigh Hyperextension.*—The patient, lying prone on a table, hyperextends the thigh, with leg fully extended, brings it down to the table again, up, and so on until this is done ten times. In order to hyperextend the thigh slowly and thus get a better action of the erector spinæ muscles, it is well to have the patient count five slowly while hyperextending, and five while bringing the limb down to the table. After a few days a sand-bag weighing from three to five pounds may be thrown over the leg near the ankle.

8. *The Key-Note Exercise.*—This consists in extending the forearm and arm of the concave side well above the head, while the other arm and forearm are extended from the side in abduction at a right angle with the body. Then let the patient proceed to rotate the arm extended above the head, from the shoulder, counting one while a complete revolution is made. This can be done ten times.

9. *Trunk Resisting.*—This is as follows. The patient stands at the end of a table or against a bar the height of which corresponds to the distance from the pelvis to the floor. The shoulders are thrown well back. The surgeon then, with his hand pressing against the convex portion of the chest posteriorly, and pressing against the back of the patient's heels to prevent slipping, pushes the patient forward over the table or bar, while the patient

offers resistance and counts five. Then the patient attempts to bring himself to an erect position, with the surgeon's hand resisting. This is done five or six times.

10. *The Diving Movement.*—The patient lies prone on a table, with the whole body extending over the end, while the surgeon or attendant grasps the legs in order to hold the patient on the table. Then, with the forearms folded over the back, the patient bends slowly down towards the floor, counting five during the act, then brings the body up to a line with the table, and so on, going through this movement from five to eight times, according to circumstances.

11. *Head Resistance.*—The patient stands erect, with the arms and forearms extended from the body towards the front, pressing the hands against the wall, while the surgeon with his hand pressing against the back of the head attempts passively to flex the head on the chest, the patient resisting and counting five. Then the patient brings the head up in extension while the surgeon's hand resists, counting five at the same time. This exercise can be repeated half a dozen times.

12. *The Four Count.*—Body erect, hands grasping dumb-bells, chest forward, hips back, shoulders well thrown back, chin drawn in. First, bring the arms up and forward from the side of the body to a right angle with the body; second, throw the arms outward, still at a right angle with the body; third, bring the arms downward and backward to strike the little-finger ends of the bells; fourth, a second strike.

13. *Anvil Chorus.*—Same position as in the above, with dumb-bells, arms in position of No. 4 as above. Strike alternately thumb ends and little-finger ends of dumb-bells, counting one for each.

14. *Wand Movement.*—Position, arms by the side of the body, grasping the wand with each hand. First, throw the arms above the head, taking care to have the wand parallel with the horizontal plane of the body; second, with the pelvis and limbs fixed, by voluntary effort rotate the trunk on the pelvis to the side opposite the convexity; third, back to second position; fourth, down to the side of the body. This movement is especially good for the rotation.

15. *Deltoid Movement.*—With dumb-bells in the hands, raise the forearms from the side of the body to the highest possible extent; then down, counting one, two.

I am indebted to Dr. B. E. McKenzie, of Toronto, for these last four exercises.

The above list comprises all that are really necessary, and as the patient gains in strength dumb-bells may be employed in most of the arm movements. I am convinced that light dumb-bells are much better than heavier ones, and the latter should not be allowed. I am using now half-pound and one-pound wooden bells. It is quite possible that the surgeon may see other exercises that will apply better to individual cases, and may find self-suspension necessary if the curve is high. At least one hour should be devoted to this list, giving the patient ample time to rest between the movements. The object in having the patient count is to avoid any over-exercise and to give the surgeon some idea as to the tax upon his patient's strength. As already indicated, it is necessary to have the patient thoroughly drilled in these medical gymnastics, and after these are thoroughly learned a home prescription may be given, which can be followed very faithfully if the mother or nurse will assist.

Any one who will consult Mr. Bernard Roth's recent work on "Lateral Curvature," published in 1889 by H. K. Lewis, of London, will find on the earlier pages some excellent illustrations of faulty attitudes corrected by the patient's own efforts. These illustrations are certainly helpful, and would be inserted here but for the fact that they represent an adult patient and are consequently unsuited for a work on diseases of children.

So far as my own observation goes in this method of treatment, I have become convinced of its utility. Just how much good it accomplishes, how much improvement can be noted, it is difficult to measure.

This brings me to a consideration of appliances for recording the amount of deviation as well as of rotation. While I have employed many forms, I am convinced that for the general practitioner nothing is better than a rough drawing made at the time he takes charge of the case, supplemented by notes as to the position of the angles of the scapulæ, the chest-expansion, the amount of lateral deviation roughly estimated, and the attitude of the patient. The skoliosometer, at best, is a complicated instrument, requiring nice adjustment, and it is seldom that two observers can make the same observations. This is unfortunate, yet nevertheless true.

Prognosis.—Practically a cure can be expected in a case wherein the osseous deformity is slight or absent. Where the osseous changes are pronounced, the deformity may be lessened but not completely corrected. The patient can cultivate a better habit in standing and sitting, and will become strong enough to maintain this improved posture without apparatus.

In order to secure the best results, the exercises must be continued daily for from two to three months under the supervision of the surgeon, and for a year subsequently at home. Often it is necessary to extend this time, and for this reason an occasional observation is necessary.

In cases where the deformity is extreme and where it is impracticable to carry out any system of gymnastics, a plaster corset or a steel brace will be found of great advantage in the relief it affords. With the more violent forms of treatment, such as that advocated by Lorenz and Beely, I have had no practical experience. In studying the literature of the subject I find little in these rougher methods to commend.

POTT'S DISEASE.

By A. SYDNEY ROBERTS, M.D.

Definition.—Pott's disease of the spine, so called from the accurate, although not the first, description of caries of the vertebræ, by Percival Pott in 1779, is a lesion of the vertebral bodies or intervertebral disks, characterized by inflammatory changes, progressive in character, and ending in total or partial destruction of the parts involved, usually terminating in ankylosis more or less complete, with the characteristic posterior deformity.

Synonymes.—Posterior curvature, Angular curvature, Spinal arthritis or osteitis; Greek, Kyphosis; French, Mal-de-Pott, Cyphose; German, Spitzbuckel. The objection to most of these terms is that they express either a pathological condition or a result of the disease, in no wise making clear or improving the conception of the trouble. It would thus seem well to retain the commonly-accepted name of Pott's disease. If any scientific term were to be adopted, Spondylitis would be the least open to objection.

ETIOLOGY.

Pott's disease is essentially a disease of childhood, although not entirely limited to this period of life, it having been found in the fœtus, in extreme infancy, in middle age, and in very old people. As a rule, however, it is most often found between the ages of three and fourteen years. Sex exerts no special influence in its production, although those who believe only in the traumatic origin of the disease speak of its more frequent occurrence in males, from their presumed greater liability to injuries.

In a general consideration of the etiology of Pott's disease it will be well to divide the subject into—

1. *Exciting causes,*—traumatisms and fevers.
2. *Diathetic causes,*—tubercle, scrofula, rheumatism, syphilis, etc.

Exciting Causes.—In the question of causation of Pott's disease, *injury* occupies so important a place in the minds of both the profession and the laity that a brief discussion of its significance as a causative factor may not be amiss in this connection.

In almost all cases presented for examination, the information is usually volunteered that the patient has received a blow or a fall. A more careful questioning elicits, as a rule, a very vague etiological description of the traumatism. Thus it often happens that in a child presenting a marked deformity the traumatism assigned as its cause is referred to a very recent period and is in character entirely out of proportion to the supposed result. There can be no doubt that, in the majority of cases presenting clinically, the relations of cause and effect, considered from the stand-point of injury, are such as in no wise to account for the symptoms presented. If it should be accepted that the most frequent causes of Pott's disease are concussions and blows, as urged by the traumatists, it would follow that many thousands of children in daily receipt of such injuries would be the victims of this disease or of some analogous joint-trouble. That this is not the fact is proved by the comparative infrequency of the disease in question. Again, the amount and character of injury are important considerations. Thus, in many children a very slight traumatism has been given as the cause of the subsequent trouble, and in many cases, if no other conditions were present, might be accepted as a definite cause. Against these may be placed the severe injuries and falls received in childhood, terminating in a short time in perfect recovery or in death. From this it follows that in the one case there must be some special or underlying condition predisposing to the production of a chronic insidious disease, while in the other case the healthy organism so modifies the process that a different result is brought about.

The fact of the matter, as it appears to me, is that injury, considered purely as a primary determining cause, has no claims to special consideration in the large majority of cases; that Pott's disease often develops without any history of such injury as would show a conclusive connection between the injury and the disease; and that at best it is but the exciting cause bringing into activity an underlying general condition, and manifested by its local expression at the site of the supposed traumatism.

Among the causes of caries of the spine which stand in the relation of direct exciting agents, the continued fevers of childhood, measles, scarlatina, etc., and in fact all depressing conditions lowering the vitality, are prominent and direct etiological factors. The same underlying condition described as giving potency to injury is undoubtedly often present, the difference in the traumatism being simply one of character and degree. The influence of a depressing poison on a tender developing bone is none the less on account of this difference in causation, although manifest often in a different manner.

Diathetic Causes.—Our knowledge of scrofula and tubercle in their causal relations to Pott's disease is as yet not of that definite character which is desirable, and therefore cannot receive more than a passing notice. When we speak of scrofula reference is had rather to a state or vulnerable condition of the tissues than to a complete pathological entity. Scrofula, therefore, we would refer to as a condition of the system rendering it peculiarly prone to chronic inflammations of a low type, retrogressive in character, and often occurring without adequate cause, accompanied by certain marked tendencies to skin-affections, glandular enlargements, and bone-disease.

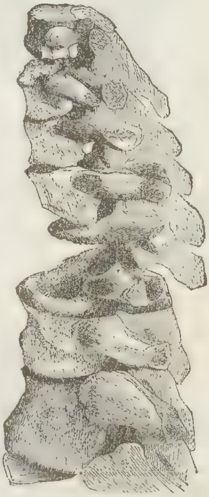
Tubercle at the present day plays so important a *rôle* in its etiological relation to bone-inflammations of the chronic type, and is of such consequence, that a detailed discussion would hardly be in place here. For a complete description the reader is referred to the article on tuberculosis, in another section of this work.

Syphilis and rheumatism may at times be diathetic conditions productive of Pott's disease, but as yet no direct evidences have been collected concerning these conditions and their manifestations in the malady under discussion.

PATHOLOGY.

Pathologically it may be well here to regard the lesions found in Pott's disease as identical with the changes found in other bone-structures in which there is tubercular caries. This is destructive in character, and may be confined to a single vertebra or may involve several. (Fig. 1.)

FIG. 1.

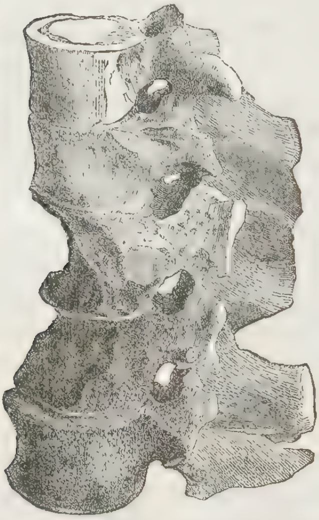


Showing extensive erosion of dorso-lumbar vertebræ.

It is in many cases attended or limited by the occurrence of a rarefying osteitis. In the strumous form of rarefying osteitis the first step in the process of inflammation is that of congestion, the bone appearing as if blood were extravasated throughout its structure; secondly there is the formation of granulation-tissue; and lastly there occurs a degeneration and softening of the new formations, with purulent exudations and absorption of bone-trabeculæ. Now the bone-corpuscles undergo fatty degeneration, and are presently destroyed, and, owing to strangulation of the vessels, caseation of the inflammatory products results. When the disease is rapid, the cancellous spaces and Haversian canals are filled with pus. The process, being a strumous or tubercular one, differs from simple traumatic rarefying osteitis, arising, as it does, from an internal or constitutional cause, or from such local irritation that a slight injury would bring it into activity. Even such injury is not necessary to provoke this strumous or tubercular caries, it often arising from no appreciable cause. A peculiar feature of this caries is its limitation to spongy bone-tissue, it rarely affecting the transverse, articular, or spinous processes primarily. (Fig. 2.)

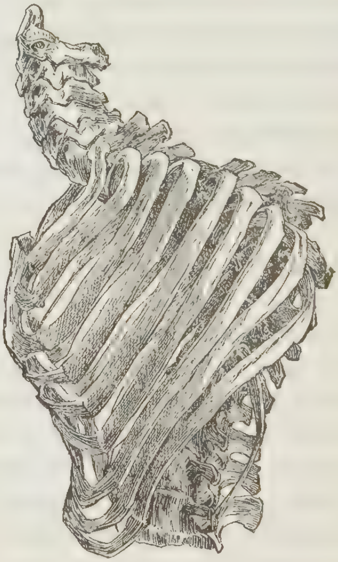
Again, this degenerative process assumes different degrees of intensity, being in some cases superficial, involving only a portion of the anterior surfaces of the vertebræ, while in other cases it not only excavates the body of the vertebræ, but also attacks the intervertebral fibro-cartilages and the adjacent soft parts, giving rise to abscess. (Fig. 3.) Not infrequently the abscess is confined within the bone, the exudation becoming purulent, the granulation-tissue breaking down, the pus and débris collecting into an abscess-cavity, and the walls of the abscess being composed of the inflamed disintegrating bone and lined by caseous pus.

Fig. 2.



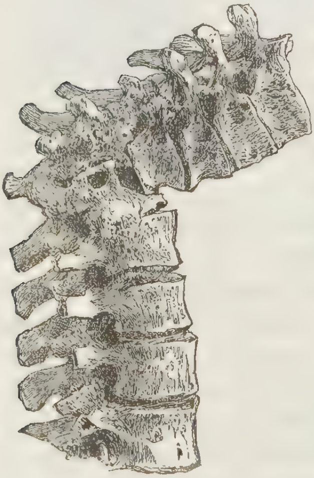
Erosion of lumbar spine, popliteal abscess, without deformity.

Fig. 3.



Characteristic "hunchback" deformity.

Fig. 4.



Marked angular curvature, resulting in compression, myelitis, and paraplegia.

It oftener happens that in rarefying osteitis the bone is absorbed in such a manner that an island of osseous substance is separated from the rest by a belt of granulation-tissue and dies, giving rise to the *caries necrotica*, but if it retains its vascular connection it forms a living sequestrum. While the bodies of the vertebræ are being absorbed, osteoplastic or protective osteitis takes place about the neural arches, being a conservative action, preventing by sudden dislocation a crushing of the spinal cord. (Fig. 4.)

A class of cases were first described by Brodie in which no suppuration took place, and these have at a more recent period been designated as dry caries, or *caries sicca.* They are identical with the so-called "osteitis fungosa" (Billroth), and are characterized by the presence of interstitial granulation-tissue growing throughout the bone. Here the granulation-tissue fills the Haversian canals and medullary spaces, and insidiously eats its way into the bony meshes. In this class of cases the granulation-tissue may undergo fatty degeneration and caseation without suppuration.

It will be readily seen that the foregoing condition differs widely from the simple rarefying osteitis, or caries, the result of injury, there being in the latter no underlying vice of the system. In this class of cases we have first a simple dilatation of the blood-vessels, followed by a pouring out of liquor sanguinis and leucocytes. In many cases the process stops at this point, and, the inflammation subsiding, resolution takes place, the parts returning to their normal contour. This limited caries undoubtedly explains the rapid recovery of many cases of so-called spondylitis following traumatism, and may also happen when Pott's disease follows one of the exanthemata, the patient being of sound constitution at the time.

SYMPTOMATOLOGY.

Before attempting to enter into a complete description of the symptoms as met with in the different regions of the spine in a case of Pott's disease, some general consideration of the different stages is of importance, and of these we will begin with the stage of invasion.

In the vast majority of cases the general health of the patient has been for a greater or lesser time below the normal standard. Even without any tubercular or strumous history or appearance that is marked, there is a condition present best expressed by the comprehensive term *malaise.* A child shows indifference to its surroundings, its usual occupations or enjoyments, and presents a listless, dejected appearance. It is easily tired and irritable, and appears sick. The appetite, previously good, becomes affected; the child loses flesh, and the skin assumes an appearance very different from the clear look of perfect health. The muscular tissues often become flabby, and the total appearance of the patient indicates that it is affected by some insidious potent malady.

Here we have the condition met with in many bone-diseases, especially where the epiphyses are principally affected, the so-called "incipient stage," or, as it has been otherwise designated, the "pre-tubercular" or "vulnerable" condition. This stage often escapes detection, the symptoms rarely being connected with the disease, and their importance being frequently overlooked. These symptoms indicate the existence of a period, and their correct interpretation at this time is of the utmost importance as regards the ultimate result of the case, this being the most favorable time to avert an increase of inflammation and prevent deformity.

Stage of Pain.—Succeeding the rather general disturbance just described, we come to a period the most important symptom of which is pain. The pain of Pott's disease varies greatly in character and extent, and its location is always dependent on the site of the inflammation.

It will be well in this connection to say a few words regarding the commonly-accepted idea that the pain of caries of the spine is always to be found posteriorly localized at the seat of the disease as manifested by the deformity. Much importance in making an examination of the spine has been attached to the recognition of this *local* pain, by means of hot sponges and other substances passed along the spinal column. Nothing could be more fallacious, experience showing that the pain of Pott's disease is referred to the posterior portion of the spine only in very rare instances.

The pain of Pott's disease is, as a rule, subacute, varying greatly in character and in degree, in many cases being intermittent, at other times being described as lancinating and intense. There is a marked relation between the rapidity and extent of the inflammation and the amount of pain. Its location may be tersely stated as following the general law that pain which is the result of nerve-irritation is reflected to its periphery. Thus, it is often found below the seat of the disease and anteriorly (*gastralgia*), but rarely above it, the exception occurring in some cases of cervical caries. As a rule, the pain is worse in the earlier stages and at night, and is aggravated by motion and position. Cases have been recorded, however, where pain has been entirely absent through the whole course of the disease.

Stage of Muscular Rigidity.—We next meet with a condition of the muscles which is of importance in both diagnosis and prognosis. This is a state of spasm or rigidity, and is supposed to be due to reflex irritation of the nerves supplying the diseased bone. Its presence is regarded as pathognomonic of osteitis. Here, as in all the large articulations, where the condition of the muscles is constantly found associated with joint-disease, its function would seem to be an attempt to mobilize the part, and is nature's effort to bring about this end. It is an early sign, sometimes appearing even before pain is complained of, and continues to a very late stage of the disease. This constitutes at times the only available symptom, and is at all times of the greatest practical importance in diagnosis when properly interpreted. It is not to be confounded with the bony rigidity found at a late period of the malady, the result of partial or complete ankylosis. This reflex muscular spasm is unique in character, and its study in connection with chronic bone-disease shows peculiarities not found in other conditions. It is an unyielding tetanoid spasm, present day and night, being, so to speak, forever on guard to prevent any injury to the diseased part. It yields only to complete anæsthesia, ordinary doses of opium or chloral not affecting it. Accompanying this spastic condition of the muscles, the result of nerve-irritation, we also have a specific atrophy, reflex in character, and noticeable at times in Pott's disease where the muscles are well developed, especially in the erector spinæ group, and progressing in direct ratio as the disease advances. This symptom is not always so easy to determine in Pott's disease as in other articulations, located more specifically, but is undoubtedly always present.

Stage of Deformity.—Although, rationally considered, the deformity of spondylitis takes place at a later period than the stages already mentioned, it is by no means unusual, especially in public practice, for it to be the first symptom of sufficient importance to attract the attention of the parents or friends to the patient, or deemed worthy of the care of the surgeon. This projection backward of one or more spinous processes is identical with that period already mentioned when speaking of pathology, where there is a breaking down of the vertebral bodies forming the anterior support of the spine. The superincumbent weight falling on the weakened support increases the projection, causes abnormal pressure on the carious and weakened vertebræ in their changed direction, and alters the normal curves of the spinal column. Where the carious process is rapid and extensive, the amount of deformity will be proportionately large, and sharp or gradual according to the amount of disease present. Where the long gradual curve is present, it shows a large area of inflammation, but not necessarily a rapid one. On the contrary, where only one or two vertebræ are involved in the carious process, the deformity is sharper and well defined. In the cervical and lumbar regions determination of the amount of disease by the appearance of the deformity is entirely unreliable, the deformity in these situations, owing to the anatomical position and construction of the vertebræ, rarely attaining the proportions found especially in the mid-dorsal spine. By some authors it is held that the shape of the curvature establishes the suppurative or non-suppurative character of the lesion. Thus, it has been maintained that *caries sicca* frequently involves a number of the vertebræ primarily, the resulting projection partaking more of the character of a true curvature, while but few vertebræ or only a single one are involved in the acute suppurative variety, giving rise to the sharp, angular deformity.

Stage of Abscess.—Among the most common of the consequences of caries of the spine is the formation of abscesses, which during their formation and course give rise to important symptoms. While these, as a rule, are more frequently met with in the later periods of the disease, the patient is at no time exempt from them, and they may occur at the earliest time, even before deformity is visible. Again, some cases run their entire course without the appearance of an abscess, while in other cases abscesses have been detected, which have disappeared without opening or giving rise to any marked disturbance. These collections of pus, coming from the carious foci, follow the general rule of the least resistance, and in their passage important parts and organs are protected by the fasciæ. It may be stated that they open at some distance from the point of origin, and according to the site of the lesion. The most common situation for the formation of these abscesses may be broadly stated to be found in connection with caries of the dorso-lumbar region. The dorsal abscesses find their way beneath the ligamentum arcuatum into the sheath of the psoas muscle, and are guided by the attachment of the sheath of this muscle under Poupart's ligament and into Scarpa's triangle, where they most commonly open and discharge their contents. Caries of the lower lumbar spine gives rise to the so-called lumbar or gluteal abscess. This has its normal outlet through the great sacro-sciatic notch, and most often points at the lower border of the gluteus maximus. Sometimes these lumbar abscesses appear posteriorly, having perforated the quadriceps lumborum, and make their appearance at or about the seat of disease. In caries of the upper or cervico- dorsal vertebræ abscesses pass in front of or behind the sterno-mastoid, or into the posterior wall of the pharynx, where they are known as retro-pharyngeal abscesses. Again, they may be found in the thorax, forming a mediastinal abscess, and discharge into the trachea, bronchi, or œsophagus, or at some external point.

While we have, for the convenience of the reader, given the usual course pursued by these spinal abscesses, it is not to be understood that they all follow these methodical directions. Indeed, their course is subject to the greatest vagaries. Thus, we have records of cases where the abscesses opened at various abnormal positions,—in the mouth, lungs, bronchi, stomach, intestines, bladder, and rectum, or in external parts remote from the site of formation. A remarkable circumstance in connection with the course of abscesses connected with spinal caries is the very rare occurrence of a fatal termination directly traceable to them. We have, however, already spoken of the protection afforded to important adjacent parts and organs by the fasciæ along which the abscess passes.

As a rule, not much disturbance of a general nature is experienced during the development and course of an abscess. The patient may have an exacerbation of evening temperature, with slight chilliness and perspiration. Pain is slightly increased, the latter ceasing, however, as the pus reaches an external situation, or where inflammation does not occur in the sac itself. The abscess may, however, occasion much local disturbance, according to its location and size. In retro-pharyngeal abscess dysphagia and suffocative attacks may be experienced, and when it opens into the bronchi there is an expectoration of pus, attended by extreme dyspnœa and collapse. All the reported cases of rupture into the peritoneum and large blood-vessels have terminated fatally. Abscesses may remain stationary for a long time, and, especially in children, give rise to very little disturbance of function or of the general health. Occasionally they are, under careful mechanical treatment, absorbed ; but, as a rule, they steadily increase in size and finally rupture.

Stage of Paraplegia.—It so often happens in disease of the lower cervical and upper dorsal region that we meet with paraplegia of the lower extremities that, while it cannot perhaps be considered as strictly a distinct stage of Pott's disease, it is still of sufficient importance to demand separate description. This paraplegia, which generally involves only the motor functions of the cord, has been usually believed to be the result of a compression-myelitis, and, while pathologically partaking rather of the characteristics of a pachymeningitis or meningo-myelitis, gives rise to such symptoms as would ordinarily result from a myelitis due to pressure, either from inflammatory products or abscess. Its onset is marked by a gradual diminution in the strength of the parts affected, until eventually there is complete loss of power, but usually little disturbance of sensation. All the reflexes are increased, as indeed they are very early, and at times it is possible to prognosticate the approach of the paraplegic condition by this exaggeration of the patellar tendon and other reflexes. Muscles which are the seat of paraplegia become rigid and tense, and at times marked clonus is easily produced, while at a later period, where the paraplegia has existed a long time, permanent contracture may result. The paraplegia of Pott's disease is a bilateral affection, and, as before stated, usually involves the lower extremities. In rare cases of dorsal caries, more frequently of upper cervical, the upper extremities may be involved. The functions of the rectum and bladder are rarely disturbed, and there is little interference with the general nutrition of the patient, atrophy taking place only in the paraplegic parts. Indeed, it not infrequently happens that many of these patients gain flesh, probably from their forced confinement in one position. Recovery is often spontaneous, and seems to be the natural tendency of this form of paraplegia. Recurring attacks are not of unusual frequency, a case having been under my personal observation where two attacks took place with recovery, and other writers report similar results. Cases have also been reported where recovery took place with marked sensory disturbance, as in a case under the author's care, where both sensation and motion were lost. As a rule, the involvement of the sensory function would render the prognosis less favorable than where there was simple motor paraplegia.

DIAGNOSIS.

It may be stated as a general axiom that diagnosis is of value proportionately as it enables us to give early and prompt treatment to the patient, and in no disease is this more pertinent than in the one under consideration. No difficulty in diagnosis is experienced where, as is, unfortunately, too often the case, patients present a kyphosis and abscess well marked, or a paraplegia in full progress. Here, however, the opportunity for relief, certainly so far as deformity is concerned, is reduced to the minimum. Where we are brought into contact with a case in which we do not find this tell-tale deformity or other marked symptom,—in other words, an incipient case,—the question of diagnosis becomes a more difficult one, and will necessitate a most careful inquiry into the symptoms, both subjective and objective, before we are enabled to arrive at a proper conclusion.

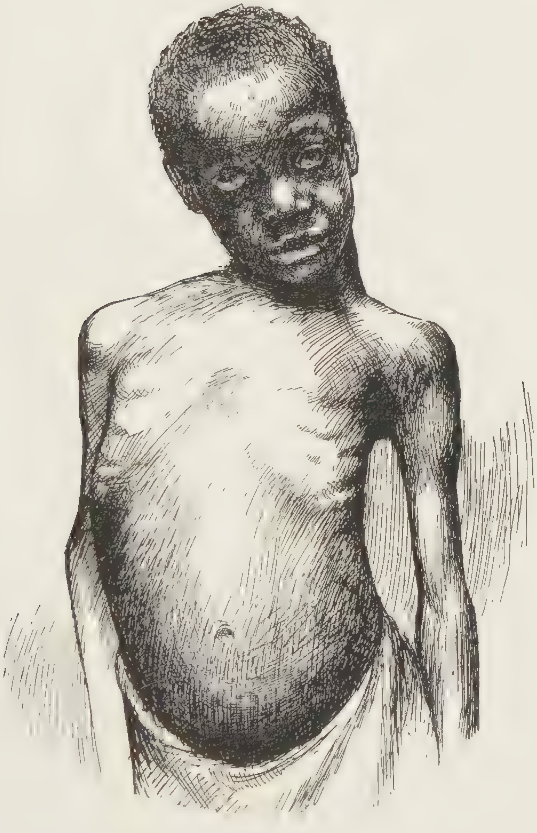
Examination of a patient presenting with symptoms which would indicate the existence of spinal caries should be conducted in the following manner. A history should be taken, according to a uniform plan, and with especial reference to certain points. The general condition, hereditary tendencies to diseases, apparent cause, and mode of invasion should first occupy our attention. Secondly, the subjective symptoms—pain, etc.—should be considered. Thirdly, the attitude and aspect will often give valuable help in diagnosis.

Most important is the physical examination of the patient, and this should be conducted as follows. The patient, after being stripped, is placed in a good light, and the surgeon, standing at his back, observes any inequalities of the spinous processes, or any deviation from the normal contour of the spinal column. In this way any marked irregularity will be at once manifest. Spinal flexibility should next receive attention. In order to have a correct perception of the spinal rigidity due to reflex muscular spasm, it is necessary that a knowledge of the normal mobility of the spine should be obtained, and this is tested best by the "Adams method," as follows. The patient, standing erect, with arms at the side, should be directed to touch the toes with the points of the fingers, the head being thrown forward on the chest. If the spine be normal, no difficulty will be experienced in performing this simple manœuvre; should there be any rigidity, the movement will be checked at a certain point. The same test may practically be applied to young children unable to stand, by placing them prone on a hard couch, the surgeon grasping the heels and elevating the whole lower segment of the body. If the spine be normal, it will be surprising to those who never have used this test, to see what an amount of mobility can be obtained in this manner. As the thighs ascend, the spine bends, in some cases enough to allow the heels to approach the occiput. This motion would be checked at some point of the normal arc were disease present, and the spine assume such rigidity that the back would rise as a whole. Lateral mobility, which in the normal spine is considerable in extent, and of great value in diagnosis, is affected in a similar manner by the presence of disease. *Taken as a whole, spinal rigidity is the most constant and valuable symptom we possess for diagnosis,* and, in conjunction with pain and attitude, often enables us to diagnosticate serious spinal caries long before the appearance of deformity.

With these few preliminary remarks, we will proceed to the study of regional diagnosis in Pott's disease.

CERVICAL CARIES.—The different regions of the spine affected with caries are characterized by widely-differing symptoms, depending upon the mobility, nervous supply, and construction of the vertebræ forming the different segments. In the cervical region we most often have disease at the third, fourth, and fifth vertebræ, and the muscular expression of disease at this point is quite characteristic. The patients hold the head rigidly in a position either of flexion or extension, greater or less according to the amount of the disease. (Plate I.) On attempting to move the head, the surgeon is resisted by marked reflex spasm in the direction either of flexion or extension, yet mobility in rotation will be found free. Herein lies a valuable diagnostic point in differentiating disease of the lower cervical from disease of the two upper cervical vertebræ, as rotation is in the latter markedly and invariably resisted. Pain is referred to the parts immediately below the diseased area. Pains radiating down the arms and in some cases to the sides of the neck, and even to the superior parts of the thorax, are most often complained of, the pains following the general rule and finding their expression at the periphery of the nerves. Jars and concussions are badly

PLATE I.



Cervical caries.

borne, and we are often enabled to observe a marked broadening of the neck. In the attempt to hold the head in such a position that concussion from jar is least liable to be felt, the spinal column below the point of disease assumes a compensatory curve, giving a hollow appearance to the dorsal part between the shoulders, with a projection in the lumbar region.

In cervical disease it is sometimes possible to feel the thickened vertebræ through the mouth, especially where the caries has advanced sufficiently to occasion some breaking down of the bodies and bulging forward of the post-pharyngeal wall, or, again, where an abscess points in this region. Paraplegia may be associated with disease of this part.

Less frequently than disease of the third, fourth, and fifth, we meet with disease of the first and second cervical vertebræ, or atlo-axoid disease. Here rigidity is quite expressive, and of itself furnishes a diagnosis. In disease between the atlas and axis all rotary movements are checked, and, while it is very rare that we have uncomplicated disease of these two vertebræ, a sufficient number of cases occur to make this limitation of motion strongly characteristic. It is in this region, although not exclusively, that we meet with the torticollis dependent on spinal caries, and this is sometimes difficult to distinguish from wry-neck due to causes independent of bone-disease, but is always a valuable aid to diagnosis. The characteristic of this symptomatic torticollis is that in spinal caries the head is rotated towards the contracted muscle, whereas in the idiopathic form of wry-neck torsion takes place away from it. Again, there is a spasmodic feeling imparted to the muscles on movement, and the posterior group are more commonly involved than the sterno-mastoid in the contraction due to reflex spasm. Ether abolishes the contraction completely. With atlo-axoid disease pain is found early in the upper part of the neck and in the occipital region, or, again, is complained of in the ears, the sides of the neck, or the upper part of the chest, and is neuralgic in character. This pain is increased by pressure on the head or by any movements affecting the upper part of the spinal column. Hilton speaks of pain in atlo-axoid disease as being always unilateral, and seems to think that this indicates the side of the vertebræ affected. Swelling and broadening of the neck also occur; marked protrusion of the pharyngeal wall can sometimes be felt with the finger in the mouth, the patient being subject to attacks of dysphagia. Deformity appears at a variable period, the patient having adopted a peculiar attitude. The head may be flexed or extended markedly, with rotation, but usually it is projected forward, and supported in every possible position by the patient, recumbency being the favorite posture. It has been supposed that deformity in this region depends upon a forward luxation of the atlas upon the vertebræ beneath, and the spinous process of the axis can often be felt or seen.

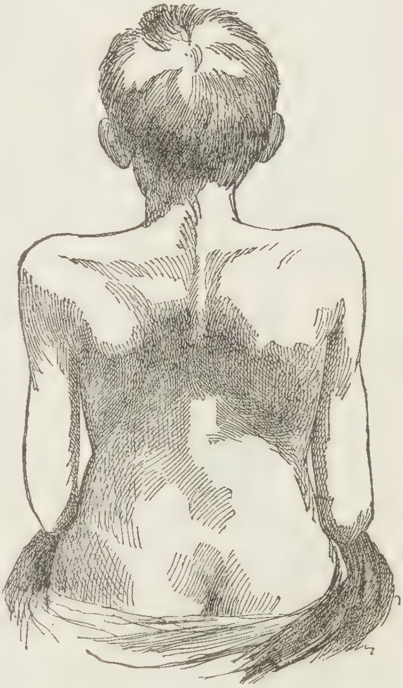
Abscesses are common in this region, and present frequently as "post-pharyngeal" collections of pus, giving rise to serious symptoms, which have received detailed description in works on surgery. Abscesses may appear also at the sides of the neck posteriorly, and follow the course of other deep-seated cervical abscesses. Nerve-symptoms are very often associated with atlo-axoid disease, varying greatly in extent, from paralysis of one arm to a more general paralysis of the parts below the neck. This is usually of the motor type, but at times anæsthesia is noticed, with loss of vesical and rectal control. Cerebral symptoms meningeal in character often occur, or sudden death may take place from crushing of the spinal cord.

Differential Diagnosis (Cervical Region).—We have already spoken of torticollis as being at times a symptom of caries of the cervical region easily mistaken for idiopathic wry-neck, and have given a rule for its differentiation. Among other diseases liable to be mistaken for this serious malady are lateral curvature involving the upper part of the spine, muscular rheumatism, simple abscess, adenitis, acute traumatic lesions, and hysterical simulation of Pott's disease. Lateral curvature is rare in this region, and is usually accompanied by rotation and marked by absence of pain and reflex spasm. It should be borne in mind, however, that a lateral deviation of the spine may take place early in Pott's disease, and in any region, but this disappears, as a rule, rapidly with the advent of bony deformity and other pronounced symptoms, and is entirely modified by treatment. Muscular rheumatism is marked by tenderness of the muscles themselves and by the entire absence of bone-deformity, and is more apt to take place at a later period of life. The movements of the neck, while stiff and painful, give no characteristic spastic sensation, and the transitory and shifting character of the affection should leave no doubt as to its nature. Simple abscesses are usually acute in character, attended by high temperature, and their history and superficial character leave little room for doubt. Acute traumatic lesions—dislocation and fracture—are diagnosticated by the history, the sudden deformity, and the usual signs of such injuries as met with in other parts of the body.

Hysterical simulation is at times exceedingly difficult to diagnosticate from true spondylitis, and may be encountered in all parts of the spinal column. In the simulated condition pain is the most prominent symptom, and is always complained of at the supposed seat of the disease, differing from that of true caries, which is generally reflected to the anterior part of the body. It has all the characteristics of an intense hyperæsthesia, and light pressure apparently gives rise to great suffering, such as is found in the so-called "spinal irritation." When attention is diverted, the pain on pressure either disappears or a new locality is complained of. There is no reflex spasm, voluntary efforts being made to keep the spine quiet, *and persistent gentle force* usually overcomes the resistance to motion. Care must be taken in estimating the amount of motion present, our diagnosis depending largely on the muscular expression accompanying the disease. Whatever bulging of the vertebræ occurs is immediately reduced by placing the patient in the prone position. Paralysis of hysterical origin is very common, and at times is difficult to distinguish from the paraplegia of Pott's disease. It is, as a rule, sudden, differing from the gradual loss of power found in the course of a spondylitis, is more often unilateral or confined to one extremity, and frequently disappears as suddenly as it came.

Dorsal Caries.—The attitude of a patient suffering with caries of the upper dorsal region suggests the attempt of one endeavoring to balance the head on the shoulders. (Fig. 5.) The chin is elevated, the spinal column below the seat of disease is straightened, and at times curved forward and held rigidly, and the gait and carriage of the patient are those of extreme apprehension. When the bony deformity is large, the head sinks betweed the elevated shoulders, giving a characteristic "turtle-head" appearance. Pain in disease of this region is referred to the chest and sides, and often there is disturbance of the respiratory function, as manifested by a peculiar "grunting," at times accompanied by cough, dyspnœa, and partial cyanosis. Interference of motion at this portion is detected with some difficulty, owing to the fact that normally here is the most rigid and unyielding portion of the spinal column. This, however, is sufficiently well marked and appreciated, especially when the other symptoms present are taken into consideration. Paraplegia is most often found in connection with disease of the upper dorsal spine, and affects chiefly the lower extremities. Reference to this has already been made, under the head of Symptomatology.

Fig. 5.



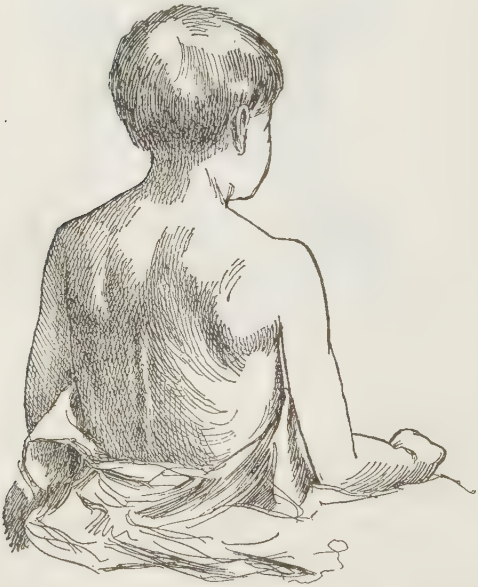
Dorsal caries.

Mid-dorsal disease gives rise to the typical "hunchback," the most persistent deformity taking place in this region. The progressive character of the lesion is due to several reasons. It is in this locality, especially the superior dorsal, that we contend with the constant traumatism of respiration, and, having a fixed projection in the middle of a flexible column, the application of proper supports becomes a matter of great difficulty. The attitude assumed by patients with disease in this region is an exaggeration of the one described under disease of the upper dorsal spine. A marked rigidity in stooping or lifting articles from the floor is noticed. The patient in performing these movements lowers the body as a whole, bending his knees and hips, and gradually approaches the article he wishes to raise, resuming the upright position with infinite care, never allowing the spine to bend. Pain is marked, especially on motion, and is referred most frequently to the lower part of the thorax and stomach, giving the "initial gastralgia" so often complained of, and at times coming on very early in the course of the disease, antedating even the appearance of the deformity. It is of great importance to realize distinctly the connection of this pain with spinal caries, as many children are treated during long periods for many different diseases,—indigestion, worms, and other disorders of the digestive tract being not infrequently assumed as the cause of the pain. The pain is frequently accompanied by the so-called "osteitic cry," and occurs most often at night, this cry being in character very much like that of acute hydrocephalus, and found in connection with disease of the bone in any part of the spine or of the articulations.

Disease of the lower dorsal spine is so intimately associated with lumbar caries that it will be best considered in the description of that region.

Differential Diagnosis (Dorsal Region).—Before the appearance of deformity causing abnormal curves to appear in the spine, aneurism of the thoracic and abdominal aorta, eroding the vertebral bodies, as evinced in two autopsies the author had opportunities of making, may give rise to symptoms similar to those of spinal caries. Diagnosis by auscultation and the presence of other symptoms usually establish the nature of this lesion before the spine is much affected and the extensive curve and localized pain are sufficient to demonstrate the existence of aneurism.

Fig. 6.



Functional spinal debility simulating caries.

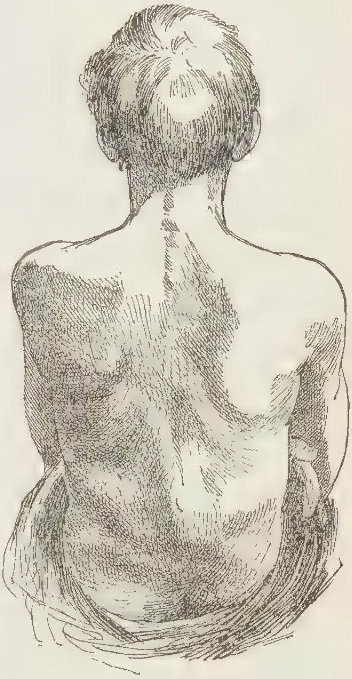
Malignant growths, cancer, etc., are rarely seen in children.

Chronic pleurisy, with effusion or empyema, and other inflammatory lung-troubles, would be excluded by physical signs.

Rachitic curves are very common in the dorsal region (Fig. 6), but are marked by their gradual character and extent, and are attended by the characteristic large head, flattened epiphyses, general tenderness, and inability to walk. Motion is rarely limited, the curvature mostly disappearing in the prone position. Pain, when present, is local in character, and the general listless appearance of the patient serves to explain the functional curve.

Disease of the Lumbar Region.—Disease of the lower segment of the vertebral column, which will here include the lower dorsal and lumbar vertebræ, presents some especially important features from the stand-point of diagnosis. It is here that we have to deal with a portion of the spine largely controlled by the psoas muscles, and the reflex limitation of motion at this point gives us most valuable indications concerning not only the condition of the vertebræ, but also the presence and progress of abscess, which is more often encountered here than in disease of any other part of the spine. Here, again, a special attitude is assumed by the patient, in most cases consisting of a "lordosis," or an anterior curvature of the spine. This is nature's mode of protecting the diseased parts, there being a conservative attempt made to throw the weight of the body from the diseased vertebral bodies on to the articulating facets. The reflex muscular spasm is best appreciated here by placing the patient in the prone position and making the movement already described in the general remarks on diagnosis. (See Fig. 7.) As stated, the condition of the psoas muscle furnishes us with excellent indications as to the presence or absence of abscess in its sheath. If, the patient being prone, the surgeon makes pressure on the pelvis with one hand, holding it firmly in one position, and, grasping the thigh with the other hand, the knee having previously been flexed, attempts to extend the thigh on the pelvis, should contraction of the psoas exist he will be met by a decided limitation in the extension of the thigh. The application of this test, one of the utmost importance, is easily learned, and, in conjunction with palpation of the pelvic fossæ and with the general symptoms of pain, temperature, etc., will usually show the presence or absence of an abscess. This limited extension is generally found unilaterally, but may be bilateral, and on the emergence of the abscess from the pelvic cavity usually disappears. Pain from caries of the dorso-lumbar spine is referred to the hypogastric region and the lower extremities.

FIG. 7.



Lumbar caries.

Paraplegia with this form of spondylitis is among the rarest of complications, for well-known anatomical reasons. Deformity, as in the cervical region, rarely reaches the degree met with in the mid-dorsal spine, and in many cases where the disease is confined exclusively to the lumbar vertebræ little or no deformity is noticeable.

Differential Diagnosis (Lumbar Region).—Many diseases may occur at or about this part of the vertebral column with spinal caries, and the knowledge and experience of the surgeon will often be severely tested in differentiating between them. Disease of the last lumbar vertebra is often mistaken for hip-joint disease, the converse being also true.

Sacro-iliac disease, perityphlitis and nephritis, sciatica, lumbago, and other diseases may also obscure the diagnosis; but space forbids a detailed account of the symptoms and methods used for differential diagnosis, the reader being referred to the articles on these subjects in other portions of this work.

GENERAL PROGNOSIS.

In general terms it may be stated that the prognosis of Pott's disease depends largely on that portion of the spinal column affected by the caries. Thus, the best results of treatment are usually obtained in the cervical and lumbar regions, at times lasting many years, although so-called acute cases have been reported. Much of the success achieved in later times in the treatment of spondylitis may be ascribed to a more correct interpretation of the symptoms, to a better knowledge of the etiology and of the mechanics of the parts, and, above all, to a better adaptation of the various supports used in the treatment of the diseased areas. Prognosis will always be affected by the amount of personal attention given by the surgeon, by the home care of the patient, and by the detail with which the mechanical treatment is carried out. During the progress of a case the symptoms may be held in abeyance for a long time, and the inexperienced surgeon, judging from the cessation of pain, the apparent arrest of deformity, and the non-appearance of abscess, may remove the apparatus, thinking his patient cured. Very soon, however, he is undeceived; the symptoms become more acute in character and assume an alarming aspect, the patient having one of the exacerbations known to every one familiar with these cases. The earlier the diagnosis is made and the child placed under mechanical treatment and good hygienic conditions, the better the prognosis. Notwithstanding the fact that the strumous or tubercular diathesis usually underlies the lesion, many patients recover, with more or less deformity, and sometimes live to advanced age. The deformity when once present rarely disappears, although it may be diminished at times by treatment.

Abscess was formerly regarded as a symptom of the utmost gravity as affecting prognosis, but many patients recover, with strong though sharply-deformed backs, who have had one or more abscesses. It is an undoubted fact that many abscesses form and entirely disappear, protective treatment modifying their course to a very large extent. Abscesses which suppurate and discharge by fistulous openings for a long time are necessarily of grave import in making a prognosis, owing to the ultimate involvement of internal organs, amyloid degenerations oftentimes causing death from kidney and liver complications.

Paraplegia, while a distressing complication and alarming alike to the parents and the attendants, is, as a rule, recovered from, often spontaneously, although usually it lasts for a long time. An exception to this is found in the paralysis attending upper cervical disease, where sudden death may take place from crushing of the cord or involvement of the respiratory centre, or, again, where motion and sensation are both involved, incurable paralysis often remains. We have discussed this complication at some length in a former section.

Death often occurs from rupture of an abscess internally, from intercurrent inflammations, such as pneumonia and tubercular meningitis, or from exhaustion following long-continued discharges. The acute exanthemata have a deleterious effect on the progress of caries, and pertussis is a particularly dangerous complication, especially in disease of the thoracic vertebræ, the affection of the spine advancing rapidly, the patient often dying in a paroxysm. Hemorrhage from perforation of large blood-vessels, and suffocation from discharge of abscesses into the lungs, have also been reported as complications with a fatal termination.

TREATMENT.

The modern treatment of Pott's disease has attained a measure of excellence attested in a high degree by the much less frequent sight of those distressing deformities which were at one time so common. Much of this is due to the improved means not only of treatment but also of early diagnosis, and to American surgery is largely due the advance in this formerly much neglected branch of medicine. In commencing the treatment of caries of the spine a consideration of the pathological state that we have to deal with is of the utmost importance. It must be remembered that there exists in this condition a retrograde rather than a reparative process, one which in its course is entirely different from the process that follows an acute traumatic lesion. Instead of its being a question of days or weeks, months and sometimes even years are necessary to effect a cure.

There being this long-continued drain on the system, it is obvious that the care of the general health should receive as much attention at our hands as the local condition, which in most instances is but the expression of a general constitutional state.

The principles of treatment to be constantly held in view should be those which aim at (1) improvement of the general health and (2) proper rest to the diseased parts, which embraces the question of correct mechanical support.

Before mentioning those remedies which have been found of service as general reconstructive agents, we would insist, in every case where it is possible, on the importance of fresh air and sunlight, the influence of which has been recognized and has largely aided in bringing about the good results of modern treatment. We have ventured to speak of these agents before mentioning the more generally used medicines, feeling, as we do, that if restricted to a choice, we should select these hygienic means as against internal medication. All such medicines as tend to "bone-building" are of value in this disease, and the selection of one—whether it be cod-liver oil, the compound syrup of the hypophosphites, phosphorus, or any of the tonics, mineral or vegetable—depends largely on the condition of the individual case and the judgment of the practitioner.

Under the second division all those means which have for their object proper rest of the diseased parts, and which include recumbency and splints or braces, will be considered. The question of rest encounters at present no dissent except from those whose experience and clinical opportunities hardly entitle them to speak with authority. On the mode of giving proper support there is still much difference of opinion.

The treatment by recumbency has had and still has its advocates; its chief merit consists in the fact that in the recumbent position, whether prone or supine, there is no superincumbent weight pressing upon the spine. Where other means are not at hand, it is well that the recumbent posture should be advised; but the utter failure of simple recumbency is easily explained by the difficulty of keeping a patient in bed, in one position, without other means. It is often necessary, even with good mechanical support, that a patient should be confined to bed, especially where exacerbations occur or a paraplegia is in progress. Thus recumbency becomes an aid rather than a mode of treatment, and in this way has a legitimate place in our therapeutics of Pott's disease. The effect of recumbency on the general health, especially in strumous cases, has been variously estimated. Many believe that, by lessening the pain and irritation, the general health has improved. Personally the results obtained by us with other means have been, as a rule, so favorable that we have not had occasion to test its merits from this stand-point.

Extension and suspension are modes of treatment which have been used for a long time, and which have recently been brought into prominence. The former has been used with advantage in cervical disease, but here again the treatment by this method necessitates the recumbent posture, and, unless under exceptional circumstances, we prefer the use of apparatus which allows fresh air and sunlight, while the patient receives proper support at the same time.

Suspension as a mode of treatment in caries of the spine is now generally used simply to allow of the application of plastic supports. As a remedial agent it is of no value independent of support. The idea formerly entertained, that by suspension pathological curves could be obliterated, no longer prevails, it having been demonstrated that, while the physiological curves may be altered or even obliterated, the gibbous curve does not change its character. Suspension should always be practised with the greatest care, and always under the direction and in the presence of the surgeon or an assistant.

Mechanical Treatment.—The plan pursued in the section on diagnosis—namely, the regional one—will be continued in the consideration of treatment. No attempt will be made to consider the numberless mechanical devices used in the treatment of Pott's disease, only those receiving attention which in the hands of the author have been found to be most easy of adjustment and modification, and which mechanically are capable of meeting the indications in the greatest number of cases. The principles underlying the question of all such apparatus as are used in the treatment of Pott's disease ought to be such as will enable us to secure certain objects. Chief among these are, first, the prevention of undue traumatism; second, the avoidance, as far as practicable, of any movement of the diseased parts; and, last, the prevention, where possible, of increase of pain and deformity. In the present state of our knowledge, there is no apparatus that will satisfactorily accomplish all these indications, and we have already stated why this lesion presents difficulties in the way of treatment, from a pathological stand-point, entirely different from those which present themselves in the treatment of an acute traumatic trouble. Were the anatomical opportunities present, as they are in other articulations, for making proper traction on the diseased parts, there could be no doubt as to the superiority of this method; but the application of continuous traction to certain localities of the spine, the subject of carious inflammation, and the limitation of such traction force, are not, in our opinion, possible.

The treatment of Pott's disease by the plaster-of-Paris jacket, as popularized by Prof. Sayre, has of late years received so many adherents and been so universally accepted as an easy mode of treating this disease that a few words concerning it and similar plastic supports will not be out of place. It is an undeniable fact that any apparatus which gives protection from undue motion and traumatism to certain diseased areas will afford relief, and for giving us a ready means of treating such localities Prof. Sayre's method is of the greatest value. This is particularly true of the dorso-lumbar region, which is the most easily controlled of any portion of the spine.

There are, however, certain disadvantages connected with the use of any plastic material, which are of sufficient importance to receive attention. The encircling of the body in any solid support prevents the surgeon from having the opportunity of carefully watching the progress of the disease, and of estimating the condition of the skin, so that it shall receive proper care. Ulcerations or abscesses may form without his knowledge, and no modification of the apparatus is possible without removal and renewal. The improvement which ensues on the application of any apparatus giving immobility is such that patients, as well as surgeons, are apt to be deceived by the amelioration of the symptoms, and hence escape the strict watch necessary in these cases. Thus the plastic envelope may be borne for months, the disease constantly advancing, and the patient returning only at rare intervals, owing to the absence of the acute manifestations. Among the poor, while it has the advantage of cheapness, the lack of cleanliness is a drawback to the use of the plaster, which those in public practice cannot have failed to notice. It is obvious, therefore, that, while possessing the advantages of economy, of needing less special experience than is required for the application and modification of steel braces, and of being entirely beyond the control of the patient, these are offset by the disadvantages already mentioned.

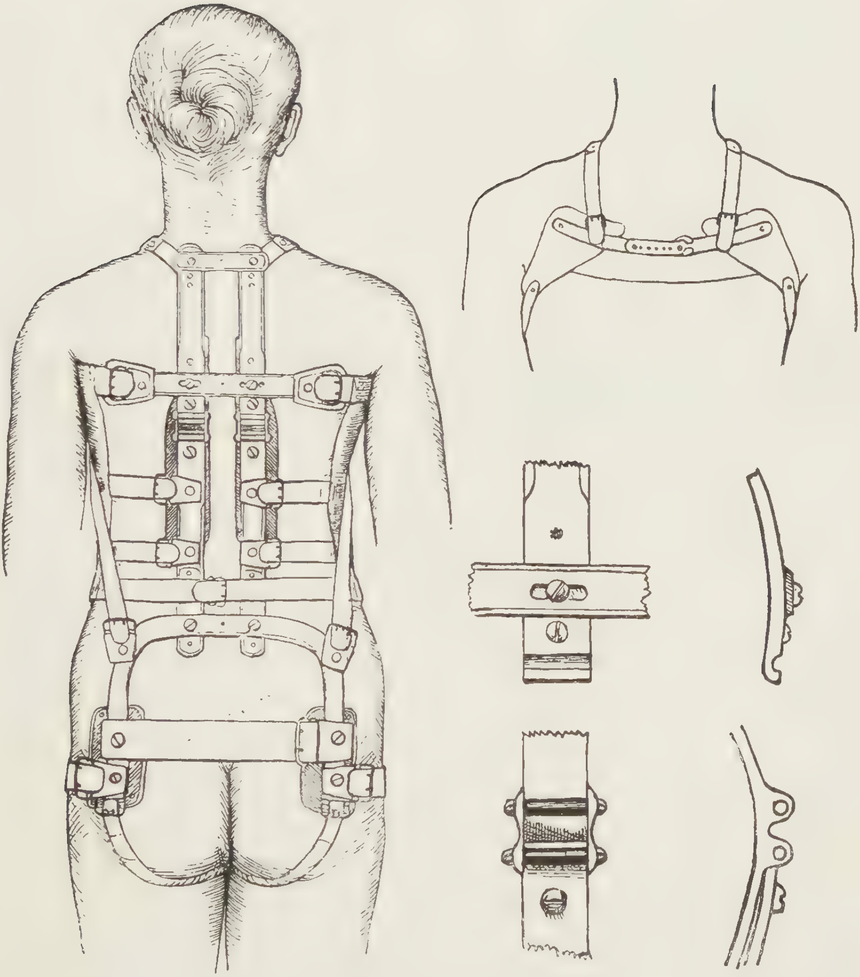
It is not an easy thing to apply a proper jacket, and it requires considerable experience to apply an efficient one, its improper application being apt to do great harm. A brief description of its mode of application will suffice here; for a fuller account the reader is referred to Dr. Sayre's work on "Spinal Disease and Curvature," London, 1877.

Suspension is obtained by securing the head in a sling, which is attached to a strong cord playing in a pulley and fastened to a staple driven into a firm place above the patient's head. The patient having previously had a tight-fitting, seamless undershirt applied, suspension is begun. The cord attached to the pulleys is so pulled that the patient's heels are raised from the floor. Freshly-prepared plaster, of the best dental variety, having been rubbed into cross-barred crinoline or other loose-meshed cloth, and rolled into bandages, is then applied. These bandages should before application be placed in water until bubbles cease to appear. The parts most liable to excoriation are carefully padded, and over the abdomen a "dinner-pad" is applied, which is afterwards removed, in order to prevent too great pressure. In females the mammæ are also padded. The bandages should be put on smoothly, and as high as possible, and there should be no inequalities or differences in thickness between the front and the back portion. After the plaster has hardened, the patient is placed on a smooth soft surface, and all rough edges are cut away, making the support as comfortable as possible. Plastic supports of different materials may be applied without suspension.

Fixative Apparatus.—Apparatus of different constructions, and representing many principles, are in use; but we have personally had such excellent results from the antero-posterior support as modified by C. F. Taylor, of New York, that in closing the account of treatment we shall speak of this alone. (Plate II.)

The anterior-posterior splint acts upon the principle of a lever, with its fulcrum at the point of deformity. The apparatus is constructed as follows. Two uprights made of the best annealed steel, allowing of easy bending and modification of shape, are connected above by a transverse bar, giving attachment for the shoulder-pieces, and below by a pelvic band. (Fig. 8.) At the location of deformity, and where we wish them to serve as a fulcrum, are placed the pad-plates, which extend for some distance above and below the deformity, and should always be sufficiently long to include the entire area of disease. These are pieces of steel slightly wider than the uprights, and are fastened to the uprights by hinges allowing of easy removal and modification. In some cases they may be screwed to the upright without hinges. They are padded with various materials, ground cork being the best. The uprights should be so widely separated that the pressure of the pad-plates will come on the transverse processes, and never on

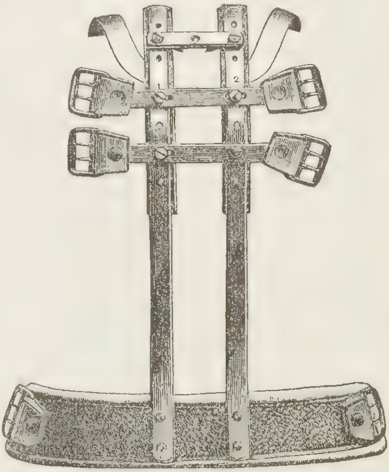
PLATE II.



TAYLOR'S MODIFICATION OF DAVIS'S SPINAL ASSISTANT. (From Transactions of the American Orthopædic Association, vol. i., 1889.)

the spinous ones. The uprights should extend high enough to give sufficient leverage, and below to the anal commissure, and the pelvic band should be broad and strong, extending from trochanter to trochanter. Cross-pieces for the insertion of buckles which are attached to the anterior support or apron are placed at points corresponding to the upper border of the axillæ and the lower angle of the scapula, and are attached to the uprights by screws. The anterior part of the support consists of an apron made of strong jean or other similar material, and this serves to fasten the trunk to the apparatus. It reaches from the upper border of the axillæ in front to a point just above the symphysis pubis. Webbing straps are attached at different points for attachment into the buckles of the cross-pieces and pelvic band, and to the shoulder-pieces are attached padded axillary straps.

FIG. 8.



Davis's spinal assistant.

The apparatus is applied as follows. The patient is placed in the recumbent posture on a hard even couch, with the apron applied to the anterior part of the trunk. The brace, previously fitted to the contour of the spine, is first secured by the pelvic band, and by axillary straps which pass to the lower cross-piece. The upper strap of the apron is then attached to the upper cross-piece. These are the important and essential points of attachment, and should always be made firm. Supplementary webbing straps and buckles may be attached to the apron to give more firmness to the support.

FIG. 9.

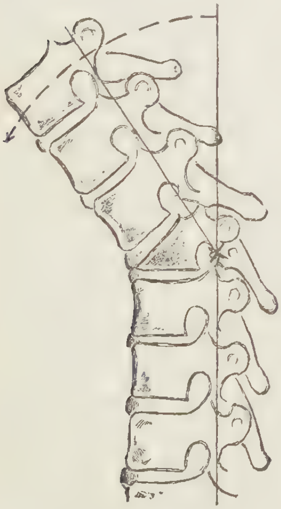


Diagram showing the principle of Davis's support.

Principles of the Antero-Posterior Support.—The antero-posterior support acts, as has already been stated, on the principle of a lever with the fulcrum at the location of the deformity (Fig. 9) and acting through the transverse processes. The pelvis is another point of pressure, forming the base of the support, and the resistance is furnished anteriorly by the superior thoracic wall and the traction of the shoulder-straps passing under the axillæ. The power is maintained by the two uprights to support the spine in the same position as is gained by the recumbent posture.

There are certain rules concerning the application of the antero-posterior brace which should be carefully followed. It should always be put on in the recumbent posture. The pressure should be entirely equable over the transverse processes, as made by the pad-plates, and the shoulder-pieces should never press on the shoulders, it being well to leave a small space between the lower surface of the shoulder-pieces and the shoulders. The axillary pads should run in such a direction that no constriction will occur on the axillary vessels and nerves. The brace should be worn day and night, unless removed for some special reason or complication, and in no case should a patient with a carious spine be allowed to assume the upright position without support. Bathing should be done by sponging the body, the patient being recumbent.

For ease of application, for convenience of modification and inspection, for comfort and cleanliness to the wearer, and for maintaining the proper pressure, we know of no apparatus which will compare with the antero-posterior brace. With a little care in adjusting the apparatus, it is within the province of every surgeon to secure with it the most satisfactory results.

Measurements for Apparatus.—It is important that the surgeon should be fully equipped not only to measure for his apparatus, but also, when it is sent to him in crude form, to be able to fit it and modify it, so that nothing is left to the instrument-maker but its manufacture.

It is measured for as follows. The patient is placed on a hard surface in the prone position. A strip of flexible lead or block-tin, which retains its form, is laid over the spinous processes from the neck to the anal commissure, and all the inequalities are carefully moulded with the lead. This is then placed on a stencil-board or ordinary pasteboard, and the inner outline traced with great care. This outline is then cut out with scissors, and marks places on the pattern for the position of the pad-plates, cross-pieces, and shoulder-pieces. The pelvic measurement is taken from trochanter to trochanter. The pattern serves a double purpose, being the guide for the instrument-maker, and also a record of the deformity at the time of measurement, and should be kept for future observation.

TREATMENT OF CERVICAL CARIES.—Under this head will be included the treatment of caries extending to the seventh dorsal vertebra, as above this point we have, in order to get efficient support, to extend the arm of the lever superiorly. This is best done by means of Taylor's chin-piece, which is secured to the uprights by means of a "keeper and pivot." (Fig. 10.) A modification of this has been devised by Dr. Shaffer, in the form of a ball-and-socket joint (Fig. 11), which allows of motion in all directions, which can be locked at any point, and in which the head can be treated in the position of deformity, and so held and modified from time to time. It is important that the chin-piece (Fig. 12) surmounting the apparatus should not be too large, and its measurement represents only the occipito-mental diameter.

In this region, it must be remembered, we are dealing with a rigid projection in the middle of a flexible column. It is thus not easy to secure adequate support, especially in the upper dorsal region, and the addition of the superior lever by means of the chin-piece is of great importance.

In the cervical region above the second dorsal vertebra, treatment, as a rule, is attended by excellent results. It is sometimes necessary still further to supplement our chin-piece by the addition of occipital uprights (Fig. 10), which increase the support. Traction-force is not attempted with the chin-piece, immobility being the object primarily in view. In some cases where the expense of a steel brace is of moment, disease in this region may be treated by means of a pedestal of plaster encircling the trunk, into which the chin-piece with ball-and-socket pivot can be adjusted. The advantages of the chin-piece in the treatment of disease of the upper portion of the spine are its lightness, firmness, and inconspicuous appearance as compared with the "jury-mast" used in the treatment by plaster of Paris for the same affection.

FIG. 10.

TREATMENT OF DORSAL DISEASE.—Disease of the dorsal vertebræ extending from the seventh to the twelfth is very common. The mechanical difficulties here, as well as in the lumbar region, are much more simple than those involved in the treatment of the upper part of the spine. We have here as a firm basis for our support the pelvis below, while the thorax and axillæ afford excellent locations for securing fixation. It is in dorsal disease that the best results are often obtained, traumatism being reduced to a minimum by the absence of respiratory and other movements, which conflict with proper support in the cervico-dorsal region. In this region sufficient leverage can be obtained by the use of the antero-posterior support without the use of a chin-piece. It is necessary, however, that the anterior support or apron should be firm, and it is often beneficial to reinforce this by the supplementary means of corsets, etc.

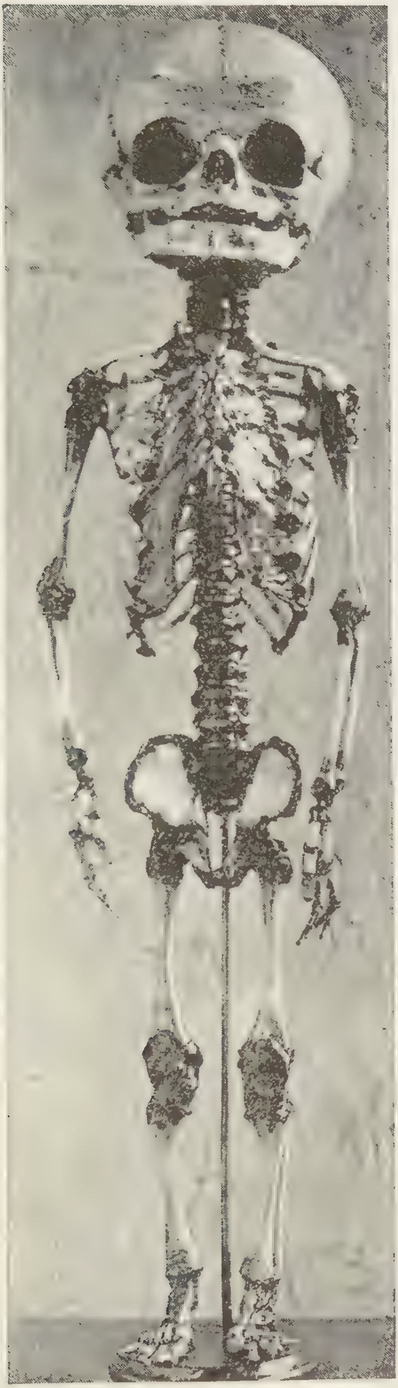
TREATMENT OF LUMBAR DISEASE.—Here the difficulties of treatment are reduced to a minimum for the same reasons as stated in speaking of lower dorsal caries. The results in this region are usually good, exception sometimes taking place in disease of the last lumbar vertebra. At times, owing to the form of the deformity, it is difficult to prevent the apparatus from pushing or slipping upward. This may be prevented by attaching perineal straps to the apron, which pass between and are fastened to buckles inserted in the pelvic band. It is especially in the lower region of the spine that any apparatus, whether of steel or plaster, providing proper fixation and support, gives real and at times instantaneous relief to the symptoms. Care must be taken here, as well as in the other localities afflicted with caries, not to remove the splint too early.

TREATMENT OF COMPLICATIONS.—Abscess and paraplegia are the two most common complications of caries of the spine. Of the former, we would simply say that for the surgical procedures necessary for their relief the reader is referred to works on surgery. There is, however, one point to which we wish to call attention. Clinical experience has taught orthopædic surgeons that the course, progress, and treatment of cold abscesses connected with Pott's disease are materially affected by mechanical treatment. Where good support of the diseased parts is given, we are sure that the development of abscesses is less common, their course is more benign, and in many instances they are entirely absorbed. Abscesses of this nature should not be opened too early, and, when opened, it is well to do so in a position suitable for thorough drainage, and under rigid antisepsis.

Paraplegia, as has been already stated, has, when caused by caries of the spine, a spontaneous disposition to recover. Its treatment is still somewhat of a vexed question. Absolute rest in the recumbent posture, with efficient support, has seemed to us to have been of most benefit. The affection being spastic in its nature, the result usually of a direct irritation of the cord, electricity in any form would be strongly contra-indicated. Suspension as a means of treating the paraplegia of Pott's disease has not, up to this date, been sufficiently tried or recorded to give any idea of its status as a treatment for this form of paralysis.

In conclusion, the question of cessation of treatment is of practical importance. With the disappearance of pain and the non-increase of deformity, as evidenced by repeated measurement and comparison of the patterns, with the disappearance of reflex spasm, allowing of free motion above and below the deformity, and lastly with the general improvement in the condition of the patient, it may be considered that solidification has taken place and that the carious process has been arrested. Relapses may occur, or disease may appear in other parts of the spine, and a careful watch should for a long period of time be kept on patients who have been the subjects of Pott's disease.

PLATE I.



SKELETON OF CHILD ABOUT FIVE MONTHS OLD, SHOWING THE LARGE SIZE OF THE CRANIUM AS COMPARED WITH THE THORAX AND PELVIS, THE STRAIGHTNESS AND SMALL SIZE OF THE BONES OF THE LIMBS, AND THE EPIPHYSIAL CONDITION OF THEIR EXTREMITIES. (Photographed by Dr. George McClellan.)

FRACTURES AND DISLOCATIONS.

By JOHN H. PACKARD, M.D.

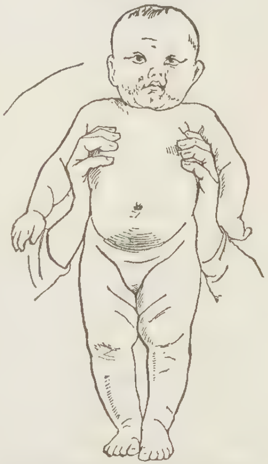
The injuries to which the bones and joints are liable in infancy and childhood do not differ essentially from those met with in adult age. Yet they are modified by the condition of the skeleton in its formative stage, and by the circumstances and habits which belong to the early period of life. Hence they present certain peculiar features, which it is the object of this article to set forth.

Every one is familiar with the vast changes in external aspect undergone by the human body in its progress from infancy to manhood; but these changes are not greater than those which take place in the skeleton during its development. In size, form, proportion, and structure, the bones of the child at birth are as different from those of a boy ten years old as the latter are from those of an adult man.

Plate I. presents a striking view of the peculiarities of the skeleton in the very young child. It will be noted that the head is proportionately very large, the thorax and pelvis are very small, and the limbs, especially the lower, are very short. The shafts of all the long bones are seen to be straight and slender; they have none of the strong ridges and other markings which appear in them in adult life; their extremities are for the most part but slightly enlarged, and are capped each with a thick layer of cartilage, at a later period to be converted into bone, as the epiphyses.

Fig. 1, from a photograph, represents a child of about the same age. The plumpness of the figure wholly conceals the slender bony framework, and is due to the thick layer of fat and areolar tissue which everywhere underlies the skin. The muscular movements are very quick, but there is no power of co-ordination, and no stress is brought to bear upon the bones.

Fig. 1.

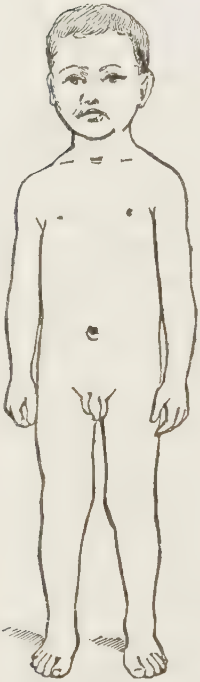


Child about seven months old. (McClellan.)

Contrasting with this the likeness of a boy four years old (Fig. 2), the bones are seen to have gained greatly in length as compared with the size of the head. The tissues overlying them are in relatively small quantity, the fatty layer being much lessened; and the body and limbs have assumed a condition fitted for the incessant activity natural to this period of life. The clavicles, as well as the extremities of the long bones at the shoulder-, elbow-, knee-, and ankle-joints, can be perceived.

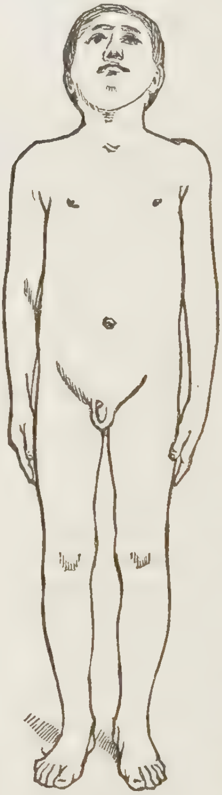
At ten years of age (Fig. 3) a further approach to the adult type may be noted. The outline of the figure seems to suggest the stronger and more decided markings of the bones and muscles; the limbs have grown more rapidly in proportion than the head and body, and the whole framework has increased; childhood is about to cease, adolescence to begin.

Fig. 2.



Boy four years old.
(McClellan.)

Fig. 3.



Boy ten years of age.
(McClellan.)

The osseous system is therefore at first in a rudimentary condition, and is actually protected by the soft parts; but its developmental changes go on rapidly, it grows up to and past them, and becomes fitted to be not only a protection to them, but also the mechanism by means of which all the outward activities of the body are carried on.

Along with its increase in size there is also a marked change in the structure of the skeleton. The walls of the shafts become thicker and denser, the cancellous structures at the extremities are more clearly defined, and the medulla is less vascular. Some of the epiphyses are still ununited to the diaphyses until adult age is fully reached.

During the whole of this developmental stage the periosteum is very thick, and its blood-supply is abundant. It is more loosely attached to the bones than after they have attained their growth, and hence in some cases of injury is stripped up to a considerable extent.

As to the conditions and habits of life in childhood, they in some respects involve more, and in others less, liability to fractures and luxations than those of adults. Children are in general more carefully guarded, and in their pursuits less called upon to expose themselves to accidental violence.

Yet they combine the heedlessness of ignorance with the timidity of weakness; they rush into dangers which they do not appreciate, and when anything befalls them they are helpless. In their plays they are reckless, inconsiderate, and venturesome; they run across crowded streets, climb trees, and in many ways expose themselves to risks which older people avoid. The very habit of being watched over by others makes them less able to take care of themselves.

On the whole, however, children are much less liable to fractures than adults are; and they are in a still greater degree exempt from luxations. Not only is the actual number of cases observed in early life less, but, as the young constitute so large a majority of the population, the relative proportion is much smaller than it would at first appear to be.

Physically, there would seem to be very little difference between the two sexes in childhood; but girls are usually somewhat more carefully watched, and they are in many cases restrained from the rougher pursuits in which boys are free to indulge. Hence after the period of infancy there is a predominance of males among the subjects of fracture and of dislocation, which becomes even more marked at puberty, and obtains throughout adult age.

There are some fractures, often met with in grown persons, from which children are almost or altogether exempt; and, on the other hand, there are some which occur exclusively in early life. In like manner there are differences between children and adults in the relative frequency of the various luxations, although here the lines are not quite so clearly drawn as they are in regard to fractures. But these points will be sufficiently discussed, and to greater advantage, in considering the lesions of each part of the skeleton.

FRACTURES.

The different bones of the skeleton vary greatly in their liability to fracture, in children as in adults. But those which are most frequently broken in childhood are not those which are so in later life. This is well illustrated in the tables given by Gurlt.[1]

From these it appears that there are from the first to the tenth year one hundred and ninety-six fractures of the upper extremities and sixty-two of the lower, and from the twenty-first to the thirtieth year one hundred and twenty-five fractures of the upper extremities and eighty-four of the lower. That is, between the first and tenth years seventy-six per cent. of the fractures involved the upper extremities, twenty-four per cent. the lower; whereas between the twentieth and thirtieth years the upper extremities were affected in only sixty per cent., the proportion of the lower having risen to forty per cent.

---

[1] Handbuch der Lehre von den Knochenbrüchen, Bd. i. p. 13.

Again, it would appear, from comparison of a number of tables from the most reliable sources, that in adults the bones of the leg are oftenest broken, then the femur, the humerus, the bones of the forearm, the clavicle, the ribs, the bones of the face (including the lower jaw), and the patella, in the order named. From the experience of the Children's Hospital of Philadelphia[1] it will be seen that this ratio does not obtain in early life. Among one hundred and four cases of fractures treated in the wards, there are noted of the femur, thirty-four, or something over thirty-two per cent.; of the forearm, twelve, or eleven and a half per cent.; of the humerus, eleven, or ten and a half per cent.; and of the tibia, nine, or about eight and three-fourths per cent. Taking these along with the cases treated in the dispensary service of the institution, we have an aggregate of five hundred and four cases, of which there were:

Of the forearm	163	Of the skull	6
" clavicle	118	" nasal bones	5
" humerus	113	" lower jaw	5
" femur	41	" scapula	3
" leg	26	" crest of the ilium	1
" fingers	17		504
" metacarpus	6		

Coulon,[2] among one hundred and forty fractures treated in one year at the Hôpital des Enfants Malades in Paris, found fifty of the forearm, twenty-six of the femur, twenty-one of the clavicle, eighteen of the elbow, and fourteen of the leg.

In the report of Langenbeck's Klinik and Poliklinik from May 1, 1875, to July 31, 1876,[3] we find some curious facts. Thus, it would appear that out of five hundred and twenty-eight fractures treated, two hundred and forty-five were in persons in the first decade of life, and only one hundred and one in persons in the second. These fractures affected the skeleton as follows:

First to Tenth Year.		Eleventh to Twentieth Year.	
Forearm	71	Forearm	51
Clavicle	70	Humerus	15
Femur	56	Leg	15
Humerus	39	Clavicle	9
Leg	9	Small bones	9
	245	Femur	2
			101

Again, Beck[4] gives the records of fifteen years' practice in the Children's Hospital in Basle. There were treated during that time, in two hundred and thirty-three children, two hundred and forty-seven fractures, distributed as follows:

---

[1] Reports, 1878 to 1887 inclusive.

[2] Traité clinique et pratique des Fractures chez les Enfants, Paris, 1861.

[3] Langenbeck's Archiv für Klinische Chirurgie, 1877, Supplement.

[4] Jahrbuch für Kinderheilkunde, 1886.

In the femur	90, or 36.4	per cent.
" humerus	52, or 21.1	"
" forearm	44, or 17.8	"
" leg	25, or 10.1	"
" clavicle	18, or 7.3	"
" cranium	7, or 2.8	"
" lower jaw	3, or 1.2	"
" finger	3, or 1.2	"
" upper jaw	2, or 0.8	"
" metacarpus	2, or 0.8	"
" pubis	1, or 0.4	"

Upon comparison of these several sets of statistics, it will be perceived that they present discrepancies for which, in the absence of details, it is not easy to account. It is probable that they depend partly on differences in the rules of admission in the various institutions, partly on the inclusion of out-patients in some of the reports, and, it may be, in a measure upon the prejudice for or against hospitals prevailing among certain populations.

ETIOLOGY.

The causes of fracture are divided into the *immediate* and the *predisposing;* the former class including all the kinds of violence under which bones give way, while to the latter belong all the conditions, whether of the system at large, of the skeleton, or of individual bones, which either expose the latter to fracturing forces, or so influence their texture as to make them yield more readily.

Immediate Causes.—*Direct violence* acts upon the bone at the point where it breaks: a blow, the passage of a wheel over the limb, any crushing force, are instances of this kind. *Indirect violence* is transmitted through some length of the bony structure, as when the clavicle is broken by a fall on the palm of the hand. Here the mechanism is often plainly leverage, sometimes a twist being also impressed upon the bone. *Muscular action,* if sudden and excessive, as in cases of convulsion, may cause fracture. *Avulsion,* or the tearing off of a small fragment of bone by stress put upon a ligament or tendon attached to it, has been observed in children in a few instances.

Predisposing Causes.—These may be considered under the head of—

Fragility of Bones.—There are some children who seem to have an especial liability to fracture; their bones are brittle, and give way to very slight forces. Certain constitutional disorders have been assigned in some of these cases.

Berkeley Hill[1] mentions the case of a child six weeks old, with symptoms of inherited syphilis, whose left humerus gave way by the mother catching its arm in a hole in the towel with which she was drying it; examination showed the right clavicle bent and deformed from a fracture at some unknown previous time. He refers to a case recorded by Porak of a fracture sustained during its birth by a syphilitic child. But these cases are certainly not common.

---

[1] Syphilis and Local Contagious Disorders, 2d ed., London, 1881.

Scrofula has been sometimes regarded as a cause of fragility of the bones, but there is no evidence that such is the fact, although Dupuytren is quoted by Malgaigne as having seen a case which was so interpreted.

Rickets, or rachitis,—a rare disease in the United States,—would seem to have been justly regarded as affording the explanation of some cases.[1]

A curious case was reported by Collins,[2] in which a deficiency of casein in a mother's milk seemed to have given rise in her child to a condition allied to rickets. This child was seen on the eleventh day after birth, when the left femur presented every appearance of having been fractured and recently united. Seventeen days afterwards the left humerus was found to be broken; three weeks later still, the right humerus, and four days after that, the right femur. Each fracture was near the middle of the shaft; all the bones were curved. Union took place readily.

In one instance, reported by Parker,[3] a girl aged six years seemed to have become the subject of fragility of the bones from general deterioration of health, the result of whooping-cough and measles.

In the same article there is a very remarkable case recorded, in which a girl of fifteen, who had a small tumor on the thigh, was descending a staircase, when the femur gave way at the junction of its middle and lower thirds. Union seemed to take place, but the bone yielded again from her starting in her sleep. On her death five months later, the place of the callus was occupied by a mass of encephaloid cancer, which had infiltrated the lower portion of the bone also; the lungs were full of cancerous deposits. I believe this case to be unique, in the youthfulness of the patient.

Sometimes there is no assignable cause, the brittleness seeming to be merely a peculiarity of structure of the bones. Arnott,[4] Stanley,[5] Gibson,[6] Goddard,[7] and Graham[8] have reported cases of this kind. In a few instances fragility of bones has seemed to be, as it were, a family failing. The girl mentioned by Arnott had had at fourteen years of age her thirty-first fracture; her sister, six years of age, had already had nine fractures. Goddard's patient, a boy aged twelve, had had fourteen fractures, his mother had had six, and his brother at thirteen had had thirteen. Graham's had had eighteen fractures in as many years, his father had had fourteen, a cousin twenty-one; and an uncle was said to be a "bone-breaker." Pritchard[1] reports the case of a child, fully developed and seemingly healthy, who when two days old was found to have the left humerus and femur fractured. On the next day the right humerus gave way from catching in the bedclothes, and at the twenty-first day the right femur was found broken. Union was progressing well at the time of the report. It is said that two uncles of this child, and three children of a brother, had been similarly affected.

[8] Boston Medical and Surgical Journal, May 15, 1884.

Three generations were thus affected in a case reported by Pauli,[2] and in another by Greenish.[3]

On the other hand, Malgaigne quotes from Saviard the case of a very young child in whom the softening was confined to the femora; and a similar limitation has been reported by Howell,[4] in a child whose first fracture occurred in its second year, the number amounting to seven by its sixteenth.

VARIETIES OF FRACTURES.

Fractures as they occur in children are classified as in adults. *Simple* fractures are such as do not communicate directly with the air; if the soft parts are lacerated by the fracturing force, by one or both of the fragments being forced through them, or by subsequent morbid process,—ulceration, suppuration, or sloughing,—so that the air finds access to the broken ends, the injury is said to be a *compound* fracture.

When portions are broken off from one or both of the main fragments, the fracture is said to be *comminuted.* If, in addition to the fracture, there is other serious lesion in its neighborhood, such as luxation of a joint, extensive laceration of soft parts, or rupture of vessels, the injury is said to be a *complicated* fracture. If several different portions of the skeleton are broken at once, as sometimes happens in falls from a great height, or in cases of crushing, the case is said to be one of *multiple* fracture.

The terms *transverse, oblique,* and *longitudinal,* as applied to these injuries, need no other explanation than that they refer to the relation of the breakage to the long axis of the bone involved.

When a bone is broken entirely through, so as to be in two portions, the fracture is said to be *complete.* But, and in children especially, the separation may involve some of the fibres only, the rest retaining their continuity, although perhaps bent; and in this case the fracture is termed *partial* or

---

[2] Quoted by Gurlt.

[3] British Medical Journal, June 26, 1880.

[4] Atlanta Medical and Surgical Journal, April, 1884.

incomplete. Another term has sometimes been used to designate these lesions; the bones so injured have been said to be *bent.* Now, the possibility of an actual bending of a bone, without fracture, has been questioned; and such a thing certainly must be very rare, occurring only in the earliest infancy. The tubular shaft of the bone is supposed to be crumpled up at the concavity of the bend, while at the convexity there is an angulation, with or without tension,—an idea which will be at once comprehended by bending a quill. But the question is not a practical one, and need not be further discussed here. What we do occasionally meet with in practice, in children, can be best defined as incomplete, partial, or "green-stick" fracture; the latter term having been applied to it more than a century and a half ago, by Turner[1] and Wiseman.[2]

Fissures or *cracks* are sufficiently described by the terms themselves, which have the same meaning as in their common use.

Sprain-fractures—described under this name by the late Mr. Callender—are those injuries which consist in the tearing off of a small portion of a bone, such as the tubercle of the tibia, by tension put upon ligamentous or tendinous structures. They are lesions not so much of childhood as of youth.

Impacted fracture is one in which the fragments are interlocked, one being driven into the cancellous structure of the other.

There is still another lesion to be spoken of, which may be said to be peculiar to childhood and youth,—*epiphysial disjunction,* or separation of an epiphysis, the breakage passing mainly or entirely through the not yet fully ossified material intervening between this and the diaphysis or shaft. There has been some objection to thus designating these injuries, on the ground that the separation is very seldom limited to the cartilage-like layer which is interposed between the shaft and the epiphysis. Richet and others declare that the cartilage and bone are continuous, and not merely contiguous. In Richet's words, "when, in consequence of violence from without, there is separation at this point, it is a veritable fracture, such as takes place in the continuity of the bones." This question is, however, one of no great importance. The fact must be admitted that in many cases there is a solution of continuity by which a growing or not fully developed bone is separated into two portions, one being the diaphysis and the other the epiphysis; and it is a matter of very little real moment whether the lesion be or be not absolutely limited to the interposed layer of cartilage. From my own observations (and I have within twenty-four hours had a case of such separation of the lower epiphysis of the femur), I should say that usually the epiphysis and cartilage are forced off, leaving the end of the diaphysis by itself. The mere fact of the detachment of a small splinter of bone from the latter does not seem to me to vitiate the character of the injury as a separation of the epiphysis. The end of one fragment belongs to the diaphysis, the other is the epiphysis, cupped and lined with cartilage, so as to fit its convex end.

Fig. 5.

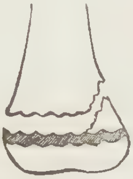

Diagram of usual form of epiphysial separation.

Fig. 6.

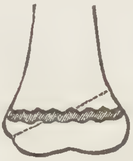

Diagram of possible form of the same.

Fig. 7.

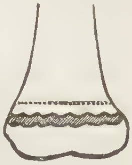

Diagram of fracture close to epiphysis.

Fig. 4 represents diagrammatically the shaft of a long bone, with its epiphysis; the shaded portion being the intervening layer of osteogenetic material. A true disjunction of the epiphysis would occur if the line of separation were to pass through this intervening layer only. What generally happens is that the fracture involves a portion of the shaft, as in Fig. 5, or a portion of the epiphysis, or both, as in Fig. 6. Or there may be a fracture through the shaft alone, very near its extremity, so that without very careful examination the mistake of supposing the epiphysis alone to be separated might readily be made. Fig. 7 is a diagram of such a fracture. In all these cases there is apt to be a more or less extensive stripping up of the periosteum from the shaft of the bone, and, whether from this cause or by reason of damage to the nutrient arteries, the subsequent growth and development of the bone have seemed in some instances to be interfered with.[1] Otherwise, these injuries do not materially differ from fractures of the ordinary kind. The subject will be again referred to in connection with the several bones.

Owen[2] suggests that epiphysial separations take the place, in childhood, of luxations. He thinks it may be assumed that an epiphysis toward which the nutrient artery runs is joined to the shaft soon after puberty; others not till about the twentieth year.

Gurlt quotes from Poupart the remarkable statement that in 1699, during an epidemic of scurvy in the Hôpital Saint-Louis, in Paris, separations of the epiphyses were very commonly observed, occurring from very slight causes, such as turning in bed. The bones seemed of more than normal thickness, and remained swollen, but without pain.

INTRA-UTERINE FRACTURES.—These injuries may be caused by blows or other violence inflicted upon the child through the walls of the mother's belly, as in a number of recorded instances. The clavicle, forearm, femur, and leg have been thus broken. Sometimes union has already taken place at the time of birth; but Mr. H. Smith has reported[1] a case in which the tibia and fibula, broken within the womb, were still ununited when the child was seven years old. In one instance, recorded by Guersant, a fracture of the leg had united at an angle, and resection was performed by Malgaigne, with a fatal result. Beck[2] records the case of a girl born with a united (intra-uterine) fracture of the leg; the two fragments had been joined at a right angle, and osteotomy was successfully performed at the age of ten months. Children have been born with multiple fractures; but in these cases there is always reason to suspect disease, or at least defective nutrition, of the bones.[3] Sometimes it would seem likely that the bones have been broken by convulsive movements of the fœtus; and in one or two instances the entanglement of the limbs of twins has been assigned as the cause of fracture. Branfoot[4] has reported a case in which, the mother having been for six weeks under treatment for acute articular rheumatism, a child was born dead, having fractures of both femora and of both bones of each leg; the broken bones were united at right angles, new bone being deposited in each case in the angle.[5]

See also an excellent article by P. Bruns, "Ueber traumatische Epiphysentrennung," in the Archiv für Klinische Chirurgie for 1882. This writer refers to a previous article, by P. Vogt, on the influence of these injuries on the growth of the long bones.

[2] Medical Times and Gazette, November 14, 1886.

FRACTURES DURING BIRTH.—These are sometimes, as in a case recorded by Vander Veer,[6] caused by the powerful expulsive contractions of the uterus. More generally, however, they are produced in the course of obstetric operations; they cannot always be prevented by the utmost skill or care on the part of the accoucheur. The humerus and the femur are especially liable to injury in this way; and the bones of the skull may be crushed in the grasp of the midwifery forceps.[7]

PHENOMENA AND SYMPTOMS.

Pain is always present in cases of fracture, though it may not be constant. Very young children, who cannot point out the seat of trouble, will merely cry and fret, until perhaps by chance it is observed that the handling of a certain part always increases their complaints.

Loss of power in the part, in some very active and restless infants, would at once attract notice; and those who have learned to speak are apt to mention this and the pain together.

Knochen des Kindes durch den Geburtshülfen, Halle, 1877; Ruge, Zeitschrift für Geburtshülfe und Frauenkrankheiten, Berlin, 1876; A. R. Simpson, On Diastases in the Bones of the Lower Extremity of the Fœtus, produced by the Accoucheur, in the Edinburgh Medical Journal, June, 1880.

Deformity, in the long bones, may or may not be present, the thick and tough periosteum sometimes holding the fragments very firmly together. Should this membrane have been torn, however, the pull of the muscles is apt to distort the limb to a very marked degree. When the existence of fracture is suspected, the child should be stripped and carefully examined.

Swelling may take place very promptly, but is sometimes only slight. One of my own children, at the age of six, had his humerus broken by direct violence; but there was no displacement until he had a fall two weeks later, and no swelling such as to attract attention at any time. His only symptoms during those two weeks were pain and loss of power.

Ecchymosis is less apt to occur in children than in adults, probably because the thick periosteum is less readily torn, and because the greater relative mass of the soft parts renders the veins less liable to rupture.

Preternatural mobility is very often to be detected. It may be at abnormal points, as in the middle of the thigh or leg, or in abnormal directions, as when the forearm can be moved laterally on the arm, or the leg on the thigh. Sometimes, as in cases of fracture near joints, or involving them, the muscular resistance may be such as to restrict mobility.

Crepitus, as in adults, affords conclusive proof of the existence of fracture. It is apt to be a softer and less distinct sound, by reason of the smallness and toughness of the bones concerned, so that their broken ends are likely to be less sharply serrated; moreover, it is masked by the comparative thickness of the periosteum, and, indeed, of the whole mass of soft parts.

Whenever there is doubt about the existence of fracture, or difficulty in determining its exact seat, it is better to give the child an anæsthetic and to make a thorough examination. Often a child will be so resolute in his resistance to the surgeon that a satisfactory knowledge of the case cannot otherwise be arrived at. With the aid of ether, and with complete exposure of both the injured and the sound side, the diagnosis may be made, reduction effected, and proper steps taken for the maintenance of the fragments in position. An essential point, in injuries about the joints, is to ascertain whether or not dislocation exists; and this is sometimes impossible unless with complete anæsthesia.

MODE OF REPAIR OF FRACTURES.

The union of broken bones takes place in children, as a general rule, with great readiness. All formative processes are especially active at this period of life, the tissues are very vascular, and the amount of reparative material deposited is apt to be much in excess of what is needed. Such superabundant callus is, however, very readily absorbed again, and it is often difficult to detect any traces of a fracture which had seemed likely to be followed by permanent deformity.

Defects in the process of repair, delayed union, non-union, and pseudarthrosis or false joint,—fortunately, not very common among children,—will be spoken of in connection with the fractures of special bones. The methods of treatment of these conditions have been so fully discussed in works on general surgery, as well as in those devoted to the subject of fractures, that it would be needless to devote space to their consideration here.

TREATMENT.

If it were possible for the surgeon, after accurate reduction of a fracture, restoring the fragments exactly to their normal relation, to hold them thus until nature should have completed the reparative process, the result would be perfect. This, of course, cannot be done; and therefore we must resort to the next best thing, by substituting for the surgeon's hands apparatus which shall keep the parts controlled and prevent the recurrence of deformity. Hence in children, as in adults, we employ splints of various kinds, fitted to the parts as accurately as possible; the immovable apparatus; sometimes extension and counter-extension.

By reason of the small size of the parts, the reduction of the fragments is generally comparatively easy in children, and they are, of course, more readily handled and lifted. But the retention is rendered difficult by the want of purchase afforded. And the restlessness of many children, with the eel-like facility which they possess in getting rid of restraint, as well as the impossibility of making them feel the importance of avoiding displacement, must always constitute an element of uncertainty as to results. Moreover, the delicacy of the skin renders it very apt to become irritated, even to ulceration, by pressure: so that special care is needful in the adjustment of apparatus.

The same general principles apply here as in the case of adults, and will be developed in the discussion of the special fractures.

SPECIAL FRACTURES.

Fractures of the Bones of the Face.—**Fractures of the nasal bones** very rarely occur in children, for obvious reasons. An accident very similar, however,—the separation of the cartilages from the bones,—is not uncommon: several instances of it have come under my own observation. It may result from falls or blows, and is attended by pain, often very severe, swelling, deformity, and abnormal mobility. Bleeding, sometimes profuse, is apt to occur, from rupture of the mucous membrane, and the contusion of the skin is followed by ecchymosis which may be very extensive. Crepitus is usually to be elicited, although it is not very marked.

Whether restored to their proper place or not, the cartilages readily unite again to the bones. Should the deformity have been left uncorrected, it becomes more pronounced as life advances, and may be a life-long source of annoyance: the utmost care should, therefore, be taken at the outset in restoring the normal relations of the parts. Boyer[1] relates the case of a girl, aged eight, whose nose was fractured by the kick of a horse; reduction was postponed until the subsidence of swelling and inflammation, but was then found impossible; and not only was the nose permanently flattened, but an incurable lachrymal fistula also resulted.

Evaporating lotions may be used for one or two days, until the first irritation has subsided. Bleeding, if very free, may be checked by pressure made with a director wrapped around with cotton and passed into the nostril; or the child, if old enough, may be induced to draw hot water up into the nose. Some children have very wide nostrils, and pressure can be readily made, in which case it is best.

When the swelling has subsided, or as soon as the state of the parts can be made out, means should be adopted for the correction of any deformity that may exist. In one case I found that after moulding the parts into shape they remained so, and no retentive appliance was needed. But if there is much mobility, a quill should be cut of suitable length, wrapped around with absorbent cotton, and gently introduced into the nostril so as to act as an inside splint. Both sides may require this treatment, and then one or two narrow strips of rubber adhesive plaster may be applied outside, so as to keep the injured parts closely confined. By means of an arrangement of this kind the interference with breathing which would ensue upon the employment of a solid plug may be avoided. Occasional inhalations of steam may be useful to prevent the blocking of the tube by inspissated mucus.

In three or four days, or perhaps sooner, the cotton becomes saturated with thin mucus, and comes away, or may be withdrawn, and another inserted in its place for a day or two, after which it may be dispensed with. But for some time it is necessary to use care, in blowing the nose, for instance, lest the displacement be reproduced.

Fracture of the lower jaw is very rare in children, the small size of the bone affording very little leverage. When it is met with, it is generally the result of a severe blow or fall. I recently saw a case in which a girl about eight years of age was thrown out of a carriage, the horses having run away; she struck her face violently against an iron post, and sustained a compound comminuted fracture of the lower jaw on the right side. Some necrosis followed, but she recovered without serious deformity. Campbell[2] has recorded the case of a boy, aged nine, who was knocked down and trodden by a horse; he had a double compound comminuted fracture of the body of the lower jaw at the left side, which united well, a few bits of necrosed bone coming away. Lonsdale says he saw the lower jaw broken at the symphysis in a child aged ten, but gives no details. Caswell[3] has reported the case of a boy, aged eight, who had a double fracture, one on each side of the symphysis, from a fall. Newland-Pedley[1] records a fracture at the side of the right lower canine tooth in a boy aged eight, who was run over. In the record-book of the Children's Hospital of Philadelphia there is noted a fracture of the lower jaw at the left of the symphysis in a boy aged four, run over by a cart. And Gregory[2] has reported a case of fracture of the lower jaw by direct violence in a child aged two years.

[3] Fractures in the Rhode Island Hospital, 1868–1878.

A good deal of shock is apt to attend an injury of this kind, and the brain may even suffer fatally. Wounds or contusions of the soft parts, within and without the mouth, are almost invariably present, and complicate the treatment. The lines followed by these fractures are very various, and not always easy to determine, on account of the rapid swelling which ensues. A greater or less degree of comminution of the bone is apt to occur.

By reason of the small size of the part, it is often difficult, and sometimes impossible, to control the fragments thoroughly, and keep them in proper relation to one another. As to mere deformity, this is not so grave a matter, as the projections of the fragments will become rounded off in time, and the appearance of the face will be better than might at first seem likely. But a more serious trouble arises from the fact that the direction of the teeth may be so changed as to prevent their accurate contact with those of the upper jaw, so that mastication will be interfered with. Hence not only should every effort be made to secure the fragments in due apposition, but the parents should be warned to have the process of eruption of the teeth carefully watched by a competent dentist, in order that any error in their position may be corrected.

The treatment consists in the coaptation of the fragments, and their retention by means of what is known as Barton's bandage. A small roller should be firmly applied in the manner shown in Fig. 8, beginning at the occiput, passing over the top of the head, down around the face, over the top of the head again to the occiput, and then around the chin to the starting-point. Along with this may be used a cup-shaped pasteboard splint to support the chin. (Figs. 9 and 10.) Sometimes, as in Newland-Pedley's case, a vulcanite plate is made to be applied over the teeth of one or both jaws; if the latter, there are, of course, two plates, connected by vulcanite

pillars. A long slip of cork, with indentations for the teeth, may be used in like manner.

Much ingenuity has been bestowed upon the invention of apparatus for the retention of the fragments in these injuries in adults, and other plans may be found discussed at great length in works on general and oral surgery.

Allan[1] refers to a remarkable case related by Morand in 1727 to the Académie Royale; it was that of a young girl who, in consequence of a fracture of the jaw, became affected with an exostosis which proved fatal.

Fractures of the upper maxillary bone are very rare in children. I have seen, in a boy aged six, a portion of the alveolar arch in front detached by a fall against a step; he bled profusely for a time, but complete union ensued. Hamilton mentions a case in which a block of wood fell upon the face of a child three weeks old, and forced the nasal processes outward.

The palatal portion of this bone would seem to be thoroughly protected from violence; but a case is reported by Griffin[2] in which a boy two years and eight months of age fell down while playing with a piccolo flute, the sharp end of which struck and fractured the hard palate. A plate was applied, attached to the molar teeth, and a good result ensued.

Sometimes, by very great violence, children sustain extensive injuries, the face being, as it were, smashed. Wiseman[3] recorded a case of this kind, in which a boy aged eight was kicked in the face by a horse. Another is related by Malgaigne, of a like accident, in which the condition many years afterwards was as follows. "The nasal bones were destroyed; the anterior portion of the alveolar arch, and most, if not all, of the vault of the palate, had likewise disappeared. He had no nose nor mouth; the two lips being fastened together by a thick and firm cicatrix, the chin was continued up to an oval opening formed between the two ascending processes of the maxillary bones as high as the frontal. By this one opening the patient breathed, spoke, ate, and drank; when a piece of bread was put into it, the tongue was seen to come up, and to carry it down to the molar teeth, which performed their functions very well."

Agnew[4] records an instance of injury apparently even more severe, but more favorable in its result. The boy was caught between two railroad-cars. "The whole face was disjoined from the head. The upper jaws were greatly comminuted, the inferior maxilla was broken into four pieces, and a number of ragged wounds involved the soft parts of the face. Notwithstanding this extensive mutilation, all the fragments of the upper jaw united; a portion of the lower maxilla, being in a great measure detached from the bone, became necrosed and was removed." The deformity remaining after recovery is well represented in Fig. 11.

Cotting[5] has reported a case in which a boy aged four years and three months was run over, a carriage containing five persons passing over his face. Besides great laceration, the right malar and upper maxillary bones were broken from their attachments, and driven downward and backward for at least half an inch. The lower jaw was broken through the body on both sides, as well as at the symphysis. The left clavicle, the second, third, and fourth left ribs anteriorly, the fourth and fifth posteriorly also, and the fourth right rib anteriorly and posteriorly, were fractured. Reduction of the fractures of the facial bones was effected; but the child died from the chest-injuries in about thirty hours.

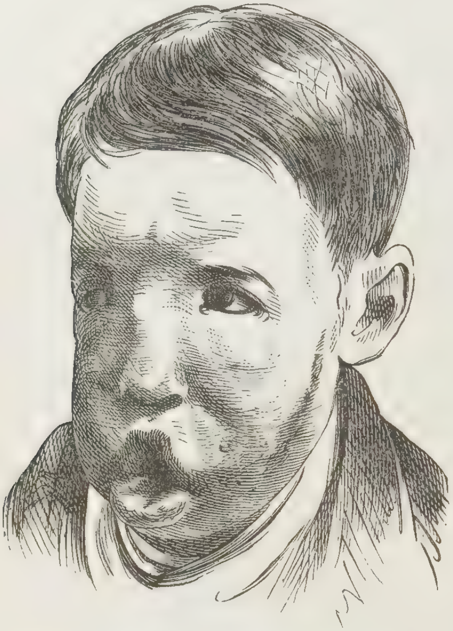
Fig. 11.



Results of a case of multiple fractures of the bones of the face. (Agnew.)

Another remarkable case, involving both upper maxillary bones, is recorded by Waechter.[1]

FRACTURES OF THE BONES OF THE TRUNK.—**Fractures of the ribs** and their cartilages are extremely rare in early life, on account of their great elasticity. Cases are upon record in which children have been run over or otherwise subjected to great violence, and the ribs have given way; but in almost every instance such other damage has been done as to prevent recovery. Thus, Fayrer[3] mentions the case of an East Indian boy, aged two, who had fracture of the left fifth and sixth ribs, with hæmoptysis, and died from exhaustion in a few hours. No details are given, but it may be assumed that the lung was wounded. Rupture of the lung has been repeatedly seen where the ribs, from their elasticity, have escaped fracture.

On the books of the Children's Hospital in this city there is noted in 1874 the case of a boy, aged five, who was caught under a falling pile of lumber and had two ribs broken on the right side. Some emphysema ensued, but adhesive strips were applied, and the boy went out cured on the sixteenth day. Another boy, aged eight, was admitted in 1875, having had the fifth right rib broken by the passage of a wagon-wheel; he was discharged cured on the twenty-fifth day. Coulon records the case of a child who died from rupture of the lung, and who was found to have sustained partial fracture of two or three ribs on each side.

---

[1] Deutsche Zeitschrift für Chirurgie, 1877, p. 106.

[2] Clinical and Pathological Observations in India, p. 223.

The symptoms of fracture of the ribs are pain, difficulty of breathing, crepitus, and perhaps emphysema. Ecchymosis may be present, and together with the history of the accident will help to indicate the seat of the lesion.

Adhesive strips of suitable width should be firmly applied over the whole of the affected side, so as to control the movements of the chest-walls. Other treatment should be instituted according to circumstances.

Fractures of the pelvis are of extreme rarity in early life. I have seen one in a boy of sixteen, who had fallen from a height; the exact seat of fracture could not be determined, but it was in the anterior portion; the urine had to be drawn off for four days; recovery was complete.

Bryant mentions an extraordinary case: "in a female child, great separation of the pelvic bones was present, the whole pelvic organs having been pressed out of the outlet of the pelvis by the crushing force. The large intestine for about a foot, uterus, bladder, etc., were all in view, the whole perineum having been ruptured." Complete recovery ensued, although, of course, with permanent damage to the parts.

In another case, that of a boy aged seven, Bryant says, there were "fracture of the pubic bones and laceration of the urethra, accompanied with profuse hemorrhage and retention, for which catheterism was ineffectual, and death seemed imminent." Free incision of the perineum down to the urethra gave relief, and the boy recovered rapidly.

A great deal of shock must follow an injury of this kind, and will demand attention; a wide bandage should be placed about the pelvis, and care taken, if necessary, to draw off the urine as it collects in the bladder. Other symptoms must be met as they arise.

FRACTURES OF THE BONES OF THE UPPER EXTREMITY.—**Fractures of the clavicle** are very common in children, and may be due to either direct or indirect violence; in the latter case the line of breakage is generally oblique from behind forward and from within outward. In the majority of cases the middle third of the bone is the part affected.

Gross[1] says that he has twice met with intra-uterine fracture of this bone, from violence applied to the mother's abdomen; and Gurlt gives seven instances of the kind. I myself saw such a case in 1859 with the late Dr. W. Keller, of this city.

Gibson[2] mentions having seen the clavicle broken during birth from an ignorant midwife pulling at the arm.

The clavicle is said to have given way to muscular action in convulsions, in the case of a boy of ten, quoted by Gurlt from Streubel, and to a violent effort at bowling in a boy of fourteen, as reported by Heath.[3]

Sometimes the fracture is incomplete. Malgaigne gives one case of his own, and quotes several others.[1] Holmes[2] gives an excellent representation of a specimen.

---

[1] Surgery, vol. i. p. 944.

[2] Surgery, vol. i. p. 255.

[3] British Medical Journal, November 18, 1882.

On the other hand, Malgaigne mentions a little girl, the subject of "a double fracture, in which the middle fragment, about two centimetres in length, was situated vertically between the two others," and could not be disengaged.

When the violence producing the fracture has not been very great, the periosteum may be untorn, and the fragments are held closely together. Yet the finger carried along the bone will detect the break, and pain will be caused by pressure at this point. And in a day or two there will be notable swelling from the deposit of callus; it seems also as if the periosteum became softened, and yielded.

When there is displacement, it is due chiefly, as in the adult, to the action of the serratus magnus muscle, rocking the scapula around forward, and through the acromion process pushing the outer fragment of the clavicle inward; the pectoralis minor will act in the same way.

As a general rule, to these symptoms, pain and perceptible deformity, there is added loss of power in the arm and hand, with more or less distinct crepitus. The child refrains from play, supports the arm of the injured side with the opposite hand, and very often inclines the head toward the damaged shoulder, so as to avoid muscular tension.

Very often the union of a broken collar-bone takes place with great readiness. Berry[3] says that in six cases, of ages ranging between five months and five years, the consolidation was found complete in from nine to fourteen days, the longest time being noted in the youngest child.

I have recently seen a girl five months old with a fracture of the clavicle caused, her mother said, by falling out of bed; crepitus was distinctly felt, but could not be precisely located, by reason of the plumpness of the parts. Union was perfect in seven days.

Non-union sometimes, however, occurs. I saw in 1857 a girl aged ten who three months before had fallen headforemost about fifteen feet upon some sand. She had an ununited fracture of the left clavicle, about one inch from its acromial end; the inner fragment was tilted backward, the outer one upward; movement of the head toward the left side was difficult. A case is mentioned[4] of "a girl aged nine who had broken her clavicle a month before, and had had no treatment; the sternal fragment projected upward at an angle of forty-five degrees, its sharp extremity forming a visible prominence at the side of the neck. The other fragment was fully an inch below this, and connected with it by what appeared to be a band of fibrous tissue passing nearly vertically between them." Pollard[1] resorted successfully to resection and wiring in the case of a child aged sixteen and a half months, the fracture having occurred five and a half months previously. Barker[2] reports another instance, in a boy aged twelve, who had, in addition to non-union, troublesome nerve-disturbances.

[3] New England Medical Monthly, March 15, 1883.

[4] Holmes's System of Surgery, 3d ed., vol. i. p. 948; American edition, vol. i. p. 846.

Fracture of both clavicles is rarely seen in children. Bennett[3] saw a case in a girl aged six, run over by a car; the fracture on one side was incomplete. Her other injuries proved fatal. Lonsdale speaks of a fracture of the collar-bone about half an inch from the sternum, in a boy aged three, who fell against a step; and says, "the other clavicle had been broken about a fortnight previously."

Holmes[4] says that he has seen a death from laceration of the internal jugular vein by one of the fragments of a broken clavicle in a child. In this case the fracture was of both bones. Such complications are infrequent; but Gross[5] saw a boy aged fifteen who four months previously had had a fracture of the right collar-bone by the recoil of a gun; "partial paralysis of the superior extremity, with atrophy and permanent contraction of some of the muscles of the arm, forearm, and hand," had resulted.

The *treatment* of these fractures has received much attention from surgical writers, and very many forms of apparatus have from time to time been proposed. I venture to assert, however, that the principle really involved is extremely simple; that the action of the serratus magnus and pectoralis minor must be opposed, and the scapula pushed round toward the median line of the back. When this is effectively done, the outer fragment of the clavicle is drawn into proper position, and the deformity disappears.

No pad should be placed in the axilla. I lay special stress on this, because the axillary pad, intended to force the shoulder outward and upward, was a chief feature in the apparatuses invented and advocated by Fox, Levis, Hamilton, and one or two others. But not only is it entirely inefficient; its pressure may do serious harm. A case is reported[6] in which a girl of eight years, having broken her clavicle, was attended by a surgeon who applied a pad in the axilla, bandaged the arm from the fingers up, and then bound the arm to the side; gangrene ensued, and amputation became necessary; a lawsuit followed, and it was held that the pressure against the pad had checked the circulation.

Sayre's method seems to me to fulfil the indications better than any other, for children as well as for adults. It consists of two strips of good adhesive plaster, of length and width proportioned to the size of the patient.

One of these is carried round the upper part of the arm, thence across the back and round the thorax; it draws the head of the humerus backward toward the median line, and thus crowds the scapula in the desired direction, the acromion carrying with it the outer fragment of the clavicle. The hand is now brought up toward the sound shoulder, and the second strip placed diagonally around the elbow and shoulder, one portion going in front and the other behind.

In most cases the inner fragment needs no attention. Occasionally, however, it has been forced forward by the outer fragment getting behind it; and then gentle pressure by means of a pad of suitable size, kept in place by small strips, may be employed to push it back into its proper position.

Compound fracture of the clavicle is of extremely rare occurrence in early life. In one case, reported by Whitson,[1] the bone was sutured, with a good result.

Schneck[2] had occasion to treat a little girl aged five who had been kicked by a colt, and who had a fracture of the clavicle complicated with fracture of the upper part of the humerus. Fox's apparatus was used for the former, and a hollowed wooden splint for the latter, the arm being confined to the side, with a perfect result in each. Foulerton[3] met with a case in which a boy nineteen months old, whose nurse pulled him by the hand, had a fracture of the clavicle and a separation of the upper epiphysis of the radius.

Fractures of the scapula are very rarely met with in children. I have myself seen one, in a little girl two and a half years old, who had fallen down three steps; the neck of the bone was broken. Another case of the same kind has been reported by Dr. John Ashhurst:[4] in both the diagnosis was made by exclusion. Gurlt quotes from Michon a case in which a child, in getting up off the ground, fractured the scapula by muscular action. I have lately had in the Pennsylvania Hospital a boy said to be two years old, but very large for that age, who fell out of a third-story window, sustaining a fracture in the shoulder-joint, probably through the glenoid cavity; crepitus was very distinct, but could not be accurately located. On the sixteenth day all trace of the injury had disappeared.

By reason of the relations of this bone, there is very little tendency to displacement when it is broken. The treatment consists in keeping the whole shoulder and arm at complete rest,—which can be done by a cap of binder's board or thick pasteboard moulded to the part, and a bandage confining the arm to the side. A carefully-applied plaster dressing would answer the same purpose.

Fractures of the humerus are very often met with in children; they may result from direct or indirect violence, or from muscular action. Any portion of the bone may give way, but in by far the largest number of cases the lower third suffers. (In adults the reverse is true, the upper portion being in them much more frequently broken.)

[4] Transactions of the College of Physicians of Philadelphia, 1875, 3d series, vol. i.

The *anatomical neck* of the humerus is reported by Fraser[1] to have been fractured by machinery, in a boy aged fifteen, the head of the bone being displaced downward; reduction of both fracture and luxation was effected under chloroform, and " perfect recovery" ensued.

But in the majority of instances in early life the *upper epiphysis* is detached, when in an adult the anatomical neck would give way. Such an accident, according to Chapelain-Durocher, has occurred during birth, from the midwife hooking her finger into the axilla and making traction. Bruns[2] collected six instances of this kind.

Hamilton mentions a case in which a child thirteen months old fell from his cradle and was said by an empiric to have sprained his shoulder. Three weeks afterward Dr. H. was called in, and detected a separation of the epiphysis, which he treated; but no union had taken place five months later.

Esmarch[3] excised the separated epiphysis in a child aged five on account of osteo-myelitis and suppurative arthritis of the shoulder.

Fuqua[4] reports the case of a boy aged ten who made a perfect recovery from what was supposed to be a disjunction of the upper epiphysis of the humerus, caused by a fall from a horse. There may be some doubt about the diagnosis in this case.

Richmond[5] reports two instances: one that of a girl aged ten, injured by falling down three or four feet on her back, and treated with a moulded leather cap over the shoulder; the other that of a young man aged nineteen, treated by first raising the arm, then bringing it down and applying extension and counter-extension by means of an outside splint. In the former case there was some deformity remaining; in the latter " a perfect result" was obtained.

Hamilton mentions two cases, in boys aged thirteen and sixteen, in which the injury was supposed at first to be luxation, and treated as such. Some shortening ensued in both; the ultimate result in the younger was unknown, but the other had a perfectly useful arm.

A remarkable case is mentioned by Bouchut as observed by Foucher. A girl aged thirteen was taking a frame down from a wall above her head, when the upper epiphysis of the humerus was separated by the muscular effort she made; an abscess formed, and death ensued in about seven weeks, when the diagnosis was established by an autopsy.

[5] New York Medical Journal, November, 1877.

Sometimes these separations are compound. Knox[1] reports such a case in a boy aged sixteen, whose horse fell on him; the end of the shaft of the humerus protruded through the deltoid muscle. Reduction was effected, and the wound dressed antiseptically; a shoulder-cap of felt and an inside angular zinc splint were applied, and the boy made a perfect recovery.

Clark,[2] in a similar case caused by a machinery accident, was obliged to amputate, the limb becoming gangrenous by reason of damage to the axillary artery. He refers to sixteen instances in which this lesion was simple, and to four in which it was compound; two of the latter ended fatally.

Separation of this epiphysis had been recognized by Sir A. Cooper,[3] and by Sir C. Bell, who says,[4] "I have known it occur from a boy firing a musket;" but it was first accurately described by R. W. Smith, of Dublin, in 1847. An important fact, pointed out by Mr. Jonathan Hutchinson[5] and myself,[6] is the rotation inward of the upper fragment by the action of the supraspinatus, infraspinatus, and subscapularis muscles. This idea was again brought forward by Dr. E. M. Moore, in a paper read before the American Medical Association in 1874, with the suggestion that the end of the shaft became caught in the concavity of the lower surface of the epiphysial fragment; he proposed carrying the arm upward and forward to the perpendicular (median?) line, and then making extension. I would venture to express my belief that a better plan is to follow the upper fragment with the lower, first by extension overcoming any impaction that may exist, and then carrying the elbow upward and outward so that the arm shall be at an angle of perhaps forty-five degrees with the body, in which position it can be readily supported by means of a splint, one branch of which should be applied to the side of the chest, the other to the inner side of the arm. After a week or two the splint may be changed so as to lessen the angle, and again two or three days later, and so on until the arm is brought down close to the body.

Helferich[7] presented to the Society of German Surgeons a successful case in which he had cut down upon the fragments, reduced the displacement, and fastened the pieces together with a long steel pin, which was left in place for a fortnight. Bruns reported two cases, and Woelfler one, in each of which excision of the epiphysial fragment had been resorted to. Such operations, it seems to me, must be rarely called for.

Bruns (*loc. cit.*) refers to two cases in which this injury, unrelieved, was followed by serious interference with the development of the bone. In one a man aged twenty had had at ten years of age a separation of the epiphysis, and the arm was shortened by thirteen centimetres; in the other, a man aged forty-nine, who in his second year had "hurt his shoulder," the shortening amounted to fourteen centimetres. Bryant mentions having seen a woman aged thirty whose arm was shortened five inches, from injury to the upper epiphysis of the humerus in early infancy. Shearar[1] saw a man aged fifty-three whose arm was shortened by four inches, as the result of a fracture near the head of the humerus, sustained at two years of age; this was probably a similar case. It is not too much to assert that accurate apposition of the fragments will be the surest means of preventing such trophic changes.

[7] Annual of the Universal Medical Sciences, 1889, from La Semaine Médicale, April 11, 1888.

Fractures of the surgical neck of the humerus are not common in early life, although they may, of course, occur as the result of direct violence. Their main interest consists in the difficulty of maintaining apposition, on account of the action of the muscles; the lower fragment is usually strongly drawn upward and inward, while the upper one is tilted over, so that the two form an angle salient outward.

Hutchinson (*loc. cit.*) says he saw a boy aged ten with fracture below the tuberosities, in whom the lower fragment was outside of and behind the upper, and was held there so firmly by bands of periosteum that reduction was impossible, even on the post-mortem table.

A boy six years old was brought to the Pennsylvania Hospital about two months since, having been struck by a locomotive and thrown about twenty feet into a ditch. He had a compound fracture of the surgical neck of the right humerus, and a simple fracture of the outer third of the clavicle. Two weeks later there was evidence of suppuration in the shoulder-joint, and excision was thought of, but a sudden improvement occurred, and all the symptoms subsided. He has now only a slight stiffness remaining in the joint.

Hamilton mentions two cases, in boys aged respectively twelve and fifteen, in both of which there was permanent shortening and deformity, but not loss of mobility or strength.

A less favorable result attended a case reported by Vogt;[2] it was that of a girl aged eleven, in whom, although there was an excess of callus, union failed to occur, and there was loss of sensation and of usefulness in the limb; excision of the upper fragment was resorted to, and electricity, but with no marked benefit, by reason, it is said, of neglect on the part of the parents of the child.

Fractures of the shaft of the humerus are not infrequent in children; they have resulted sometimes from obstetric operations, and occasionally from the compression caused by the contractions of the womb.

Powell[3] saw in a child four days old a fracture at the middle of the humerus, caused by rough handling on the part of a nurse. Prewitt[1] was called to a female child six days old who had a fracture of the humerus at the junction of the middle and upper thirds, said to have been caused three days before by the mother lifting her; there was some doubt whether the injury had not occurred during birth.

[2] Deutsche Zeitschrift für Chirurgie, 1877.

[3] Medical Bulletin, January, 1884.

Campbell[2] reports the case of a boy sixteen days old who fractured the humerus near the middle by falling out of bed; good union took place in three weeks. The treatment is stated to have been by means of a gutta-percha splint, with a pad on the inner side of the arm, the limb being bound to the chest with adhesive plaster and bandages.

In older children blows, falls, and violence of various kinds produce these injuries. Sometimes, but rarely, they are compound; I have had to amputate the arm of a boy only seventeen months old for railroad crush, and he completely recovered. In a number of instances, in early life, the humerus has given way under muscular effort in throwing. Bellamy[3] records one at the age of fourteen; Perrin[4] one in which the same boy twice broke his humerus in the lower third in this way, a year's time intervening between the two accidents.

Occasionally in these cases the periosteum is untorn, and holds the fragments together; but there is pain, helplessness of the limb, and tenderness on pressure. Usually, however, the mobility at the seat of fracture makes the diagnosis clear. One of my own children, at the age of six, had his humerus broken in the lower third, by direct violence; but it was not until two weeks later, when he had a fall, that the fragments were disjoined. Raleigh[5] reported a similar case in a boy aged nine years.

Complications of these fractures are not often met with in children; but Laurent[6] gives a case related to him by Richet, in which a boy aged ten fell off an ass, and broke the humerus at the middle; next day a small pulsating tumor was noted, evidently an aneurism caused by wound of the artery by one of the fragments. Ligation above and below was practised, with a good result. Stamforth[7] is reported to have shown to the Sheffield Medico-Chirurgical Society a girl twenty-one years of age with atrophy of the deltoid, supraspinatus and infraspinatus, biceps, and brachialis anticus, supposed to be due to "a green-stick fracture of the humerus over nineteen years previously."

The treatment of fractures of the humerus has varied greatly in different hands. I shall only mention that which I have always found effective. A splint of light wood, of sheet zinc, or of binder's board should be adapted to the inner side of the arm, the elbow being flexed at a right angle; this splint should extend from well up in the axilla to the ends of the fingers, the upper end of it being rounded off. Three small splints of zinc or binder's board should next be cut out, one for the back of the arm from the shoulder to the elbow, one for the outer side, and one for the front. Each of these is now to be carefully padded with an even layer of clean, raw cotton, or with two to four layers of canton flannel. Just at the elbow, in the inside splint, a hole should be cut for the epitrochlea or inner condyle, or else a pad should be placed just above, so as to prevent pressure on that bony prominence. Reduction being now carefully accomplished, the splints are applied, and secured by a roller bandage, beginning at the fingers and ending at the shoulder. The turns should be put on as accurately as possible, just tightly enough to keep the entire limb at perfect rest. The whole is now suspended from the neck by means of a sling.

[7] Lancet, May 25, 1889.

When the fracture is above the middle of the bone, it may be well to substitute for the three small splints a pasteboard cap, accurately cut out, softened, and fitted so as to extend from the tip of the shoulder to the elbow, embracing a little less than two-thirds of the circumference of the arm. Between this and the inside splint, I have never found it difficult to control the fragments.

Cases of delay or failure in union are more frequent in this bone than in any other part of the skeleton. Mott[1] reported an instance in which a boy of twelve had a fracture which after the lapse of eight months had not united, the ends of the fragments having become conical; setons were twice used, but failed; the ends were then cut down upon and sawn off, and the surfaces of bone wired together, with excellent success.

White is credited with the first resection in a case of this kind, in 1759; but he says[2] he was not the operator; the result was perfect.

A very curious case has been recorded by Clarke,[3] of a fast-growing boy who had a fracture of the arm, which united; he returned to school, overworked himself in trying for a prize, and broke down in health, when the fragments were found to have become disjoined.

In the Warren Museum[4] there is a specimen (No. 1314), from a boy fifteen years old, of the lower six and a half inches of the humerus, necrosed after fracture of the bone and compound dislocation of the elbow. After the removal of the sequestrum, healing took place, and "when heard from four or five years afterwards, he had a good arm, and sufficient motion at the elbow."

Fractures of the Lower Portion of the Humerus.—Close above the elbow, where the humerus widens out, becoming thinned antero-posteriorly, fracture very often occurs in children, and is apt to be followed by permanent disability.

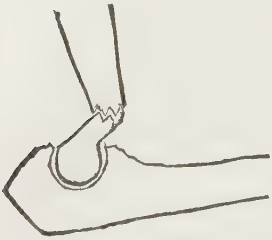
The short lower fragment is tilted forward by the action of the flexors, pronators, and extensors, aided by the upward pull of the triceps, the biceps, and the brachialis anticus upon the radius and ulna. Hence there is formed between the two fragments an angle salient forward; and unless this is corrected it will be found, when union has taken place, that flexion of the elbow is limited, for an obvious reason. (See diagram, Fig. 12.) Of this I have myself witnessed repeated instances. A clear description of this state of things, with an illustrative case, in a boy aged eight years, is given by Coulon.[1]

Fig. 12.



Verneuil, in a discussion at the Société de Chirurgie[2] in Paris, mentioned a boy aged twelve who by a fall from a horse had the humerus broken at its lower part. There was good union without deformity, but the radial nerve was paralyzed. Four months later the arm and forearm were shrunken, and the lower fragment was almost doubled in its antero-posterior diameter. The elbow had been kept immovable for seventy days. Extension was possible to one hundred and thirty degrees, flexion only to ninety degrees. Pronation and supination were free.

From luxation of the elbow backward, which it much resembles, this injury may be distinguished by three points. First, there is apt to be distinct crepitus, easily perceived. Secondly, there is abnormal mobility in every direction; on grasping the arm with one hand and the forearm with the other, the surgeon will find not only flexion and extension free, but the forearm movable also from side to side. Thirdly, the olecranon will be found to preserve its normal relation to the epitrochlea and epicondyle.

I have in one instance seen this fracture compound, in a boy about twelve years old, who had fallen from a low fence; the artery was torn across, and I was obliged to amputate.

Lange has recorded[3] the case of a girl aged eight, who after a fracture close to the lower end of the humerus had pain at the seat of injury, the wrist and fingers being flexed, with a very limited degree of motion. A sharp edge of bone could be felt. An incision was made, and the median nerve found flattened against the edge of bone; above this point the nerve was thickened. The nerve was loosened, and the edge of bone excised, with decided relief. A curious point is that in this case the growth of the nails was interfered with previous to the operation.

Various plans have been recommended for the treatment of these cases;

---

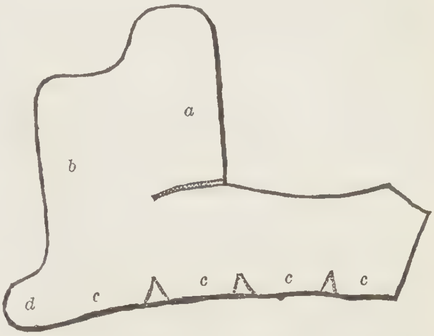
[1] Op. cit., p. 136.

[2] Bull. et Mém., 1880.

[3] New York Medical Journal, April 28, 1883.

but I shall mention only one, devised by me many years ago, which meets the indications, and which has given me the best results. Measuring by the sound limb, I cut out a piece of binder's board, or in a very young child a piece of pasteboard, in the shape shown in the diagram (Fig. 13). This is then again cut in the dotted lines, and it will be seen that *a* can be turned over so as to fit along the front of the arm, while *b* will be on its inner side, and *c* on that of the forearm. The portions *c*, *c*, *c*, *c*, turned up, will steady the forearm and hand, while *d* is turned up so as to push forward the olecranon and with it the lower end of the lower humeral fragment. Properly padded, this splint is secured by means of a bandage accurately applied from the fingers to the shoulder, and the hand and forearm are supported by a sling.

FIG. 13.



My own practice is, in this as in all other fractures near joints, to begin very early with passive motion. Thus, a week after the injury I very firmly grasp the limb at the seat of fracture, and gently flex and extend the joint through a small arc, avoiding the infliction of any pain. The joint has not yet stiffened, and the fracture can be controlled. At every dressing this manœuvre is repeated, through a larger and larger range.

I think it is well also, at the end of fourteen to sixteen days, to cut away the hand part of the splint, and let the little patient begin to move the fingers. A week later, the whole hand can be left free; and by the time the splint is removed, the limb will be almost restored to usefulness.

No prudent surgeon will forget, in dealing with a fracture of this kind, that there is danger of gangrene from interference with the circulation in the brachial artery. Sometimes this has been unavoidable, the vessel having been pressed upon by the end of the upper fragment; but an ill-adjusted splint, or a bandage too tightly applied, may increase the evil, and, no doubt, has in some instances given rise to it.

Malgaigne mentions a remarkable case seen by him; it was that of a little girl two years old, in whom a fracture just above the lower end of the humerus, sustained several months before, had wholly failed to unite.

Separation of the lower epiphysis of the humerus, although much like the injury last mentioned, differs from it in the absence of any peculiar tendency to displacement. Farabeuf[1] has discussed the anatomy of this lesion, which he thinks must be very rare after the age of four years. At birth the whole of the lower end of the bone is cartilaginous, and ossification begins first in the condyle at the end of the second year.

---

[1] Bull. et Mém. de la Société de Chirurgie, 1886, vol. xii.

According to Gray, the lower epiphysis of the humerus is developed as follows: "At the end of the second year, ossification commences in the radial portion of the articular surface, and from this point extends inward, so as to form the chief part of the articular end of the bone, the centre for the inner part of the articular surface not appearing until about the age of twelve. Ossification commences in the internal condyle [epitrochlea] about the fifth year, and in the external one [epicondyle] not until between the thirteenth and fourteenth years. About the sixteenth or seventeenth year, the outer condyle [epicondyle] and both portions of the articulating surface, having already joined, unite with the shaft; at eighteen years, the inner condyle [epitrochlea] becomes joined."

My belief is that in young children the leverage exerted through the ulna sometimes twists off the whole or a portion of the epiphysis; for I have repeatedly observed, in subjects less than five or six years old, injuries of the elbow in which there was crepitus, and yet no traceable line of fracture; a certain looseness of the joint, and helplessness of the limb, which have seemed to me to admit of no other explanation. These cases have always done well with very simple treatment,—an angular splint for the front or inner side of the arm, with early and thorough, though very gentle, passive motion. Wight[1] met with a curious combination of injuries in a boy aged eight, who fell from a cart and sustained a fracture of both bones of the forearm less than an inch (two centimetres) from the wrist, together with separation of the lower epiphysis of the humerus. Passive motion of both joints was begun on the third day, and good union was obtained, although at the time of the report the movements of the elbow were still somewhat hindered by excessive deposit of callus.

Maisonneuve[2] met with a compound separation of the lower epiphysis of the humerus, the shaft projecting some distance through a large wound. The patient, a boy aged seven, had fallen about ten feet. Reduction was effected with some difficulty; in three months the wound healed, and a complete recovery ensued, but not before eighteen months had elapsed.

Among English and American writers there is a somewhat awkward confusion of terms in regard to the lower extremity of the humerus. The term "condyles" has been applied by anatomists to the tuberosities at the outer and inner sides, and has been so used also by surgeons, who have, however, often included in it the adjoining portion of the articular surface. Indeed, the whole of the trochlea has been sometimes spoken of as part of the inner condyle, and the rest of the joint-surface as belonging to the outer; while fissures running down into the joint have been termed "intercondylar." Such confusion may be avoided by adopting the French nomenclature, and speaking of the trochlea and epitrochlea, the condyle and the epicondyle.

Fractures of the epicondyle have been observed in children. A typical case of this injury is recorded by Coulon,[1] in which a boy aged three and a half years fell from a chair to the ground; the broken piece, very small, was distinctly felt. The arm was simply kept on a pillow, and compresses soaked in tincture of arnica applied; consolidation had taken place on the twelfth day, and all the movements of the elbow-joint were perfect. But in many cases, although there is detachment of the epicondyle, this is only a portion of the injury, the elbow being dislocated, or the joint-surface being also involved. Coulon reports two other instances of what he calls intra-articular fractures of the epicondyle, one in a boy six years old, another in a boy of fourteen; both these cases resulted in serious deformity and disability, and should be classed with fractures of the elbow.

---

[1] Annals of Anatomy and Surgery, October, 1880.

[2] Clinique Chirurgicale, tome i. p. 533.

Fractures of the epitrochlea are much more common. Coulon gives three instances, two in boys aged ten and a half and eleven respectively, and one in a girl aged three and a half. In all, the injury was readily recognized, and the movements of the joint were completely restored, or almost so, in a short time. The same may be said of a boy aged eleven seen by Hamilton, as well as of a girl aged thirteen, and a boy aged eleven, mentioned by Stimson.

The fragment in such a case may be displaced either upward or downward (toward the wrist). Sometimes it remains loose. As the flexors and pronators take their origin partly from the epitrochlea, the lesion may sometimes at least be in the nature of a sprain-fracture, the fragment being torn away; and the same fact may explain the displacement in some cases. Occasionally, perhaps, the piece may be pulled away by stress on the internal lateral ligament.

When the articulation is invaded, as in what Coulon calls intra-articular fracture of the epitrochlea, the results are very grave. In four instances cited by him the loss of motion in the joint was such as greatly to impair the usefulness of the limbs. Granger[2] first described this injury, giving an account of two cases, both due to falls on the hand. One of the patients, a boy aged eleven, had also a luxation of the elbow, which was reduced; but, by reason of neglect, he failed to recover flexion and extension in the joint. In the other case, that of a boy aged eight, the fragment was retracted below the joint; there was such irritation of the ulnar nerve that the muscles supplied by it were paralyzed, and crops of vesicles appeared in the skin in that region; the use of the hand was, however, ultimately regained.

It seems to me that in both these instances, certainly in the first one, the fracture must have entered the joint; and if a portion of the trochlea is broken off, the occurrence of luxation of the forearm backward, or backward and inward, is greatly favored. Among the recorded cases I find but one, quoted by Gurlt from Senftleben, in which the result is said to have been good; it was that of a boy aged eleven. Gurlt cites from Langenbeck the history of a boy aged ten, whose elbow was ankylosed; on resection the broken condyle (trochlea?) was found in the olecranon fossa; death ensued from pyæmia. The same surgeon has reported the case of a boy aged seven, in whom the luxation was reduced, but the joint was permanently stiffened. In the Warren Museum[1] there is a specimen from a girl aged sixteen, who had a fracture of the inner condyle (trochlea?) with dislocation backward and outward of the elbow. Sloughing ensued, and amputation was performed on the forty-sixth day; "the condyle is seen to have undergone considerable change, as have also the other bones, more or less."

---

[1] Op. cit., p. 143.

[2] Edinburgh Medical and Surgical Journal, April, 1818.

Let it be noted that the same muscular violence which is charged in some instances with tearing off the epitrochlea would also, through the ulna, be very apt to wrench away a portion of the trochlea itself.

The symptoms of fracture of the trochlea need hardly be discussed in detail; they are, indeed, often masked by the swelling which so rapidly ensues upon the receipt of the injury.

As to the treatment, it must be directed first of all to the allaying of inflammation in the joint; I think free leeching, with the employment of evaporating lotions for a few days, highly advisable. On the subsidence of the swelling, the deformity should be carefully corrected, and the limb placed at rest with the elbow well flexed. Passive motion should be begun early, and carried out thoroughly but very gently every day. This seems to me of more importance than anything else. I myself employ the splint shown in Fig. 13 (p. 1069); if an anterior angular splint is preferred, a short posterior splint applied from the middle of the upper arm down to the point of the elbow may be added, in order to press the olecranon, and with it the fragment, forward.

Fractures of the condyle are by no means uncommon in children. Hamilton (1880) says that of twenty-nine cases recorded by him, twenty-seven were in patients under fifteen years of age.

Direct violence may give rise to this injury; or, if the hand is fixed with the elbow in flexion, and a blow is received low down on the back of the arm, the condyle may be forced off by the head of the radius.

In a case shown by Bidwell[2] to the Hunterian Society, a boy aged five had had a fall on the hand thirteen weeks previously. He was said to have dislocated the elbow, and splints were applied for three weeks. When shown, there was deformity, widening of the elbow, and very little motion; the outer half of the articular extremity of the humerus, displaced forward and outward, was firmly united. It seemed obvious that the condyle had been forced off by the upward thrust of the radius. Excision of the joint was proposed.

Compared with fracture of the trochlea, that of the condyle is much less serious, since it does not affect the portion of the joint which is essential to its stability. The fragment, and with it the head of the radius, is apt to be displaced backward, or backward and outward. Usually it can be easily replaced, but often there is difficulty in retaining it.

---

[1] Catalogue, p. 172.

[2] Lancet, May 4, 1889.

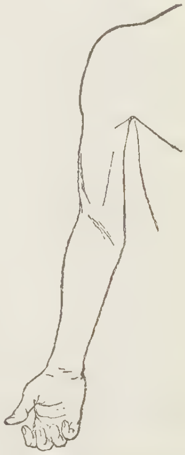
The diagnosis may be made by exclusion, but is rendered certain if the fragment can be grasped and moved upon the rest of the bone.

As to treatment, the elbow may be flexed and the hand supinated, and an anterior or a posterior angular splint applied. Early and frequent passive motion should be made. Even if union fails to occur, the strength and functions of the limb are not likely to be seriously and permanently impaired.

In a case recorded by Wright,[1] a strumous boy aged twelve had a fracture detaching the condyle, upon which there ensued a pulpy degeneration of the joint, demanding excision.

One point should never be overlooked in any case of fracture at the lower portion of the humerus, but especially in separations of the trochlea: there is apt to be caused a change in the relation of the arm with the forearm, which seriously impairs not only the shape but also the usefulness of the limb. Normally, if the elbow is extended with the hand in supination, the forearm forms with the arm an obtuse angle salient inward, toward the median line of the body; and the fold of the elbow in front curves obliquely downward and inward. (Fig. 14.) The reason of this is the obliquity of the trochlea. If now a splint is applied which presses straight across, it pushes up the lower and more movable fragment, and the result is that the forearm either comes into a straight line with the arm, or even makes with it an angle salient outward. Union taking place under such circumstances, as pointed out long ago by Dorsey,[2] and later very forcibly by Allis,[3] there will be at all times a very notable awkwardness in the limb, besides marked interference with its strength and usefulness in many of its functions.

Fig. 14.



Normal relation of arm and forearm in extension and supination.

In order to obviate this difficulty, Allis and others have proposed treating these fractures with the limb in the straight position. I think a better plan is to make a splint which shall conform to the normal shape of the joint, and to keep the hand away from the body. This is not always easy to do; and, indeed, one may often see these fractures dressed not only with the hand in supination, but with the forearm carefully drawn forward and slung as close to the front of the body as possible. Fig. 15 shows a splint of a shape such as I have often used with satisfaction; it can be made of wood, of tin or zinc, of binder's board, or of wire netting.

Fig. 15.

[3] Annals of the Brooklyn Anatomical and Surgical Society, August, 1880.

The opinions of surgeons have varied greatly in regard to the treatment of fractures about the elbow. Desprès[1] has advocated the use of a simple sling, with poultices; but was strongly opposed by Sée, Verneuil, and Lannelongue, who thought the immovable apparatus should always be employed. Sée mentioned the case of a child treated without splints, with a very bad result, the elbow being ankylosed and greatly deformed. Verneuil and Lannelongue thought there was great risk of hyperostosis under any treatment.

Illingworth[2] has recommended the employment in these injuries of a "box-splint," the limb being placed in extension, with the hand pronated. It seems to me that this would rather promote the formation of the angle salient forward.

Besides the forms of fracture now specified, there are cases of general smash of the bones entering into the elbow-joint. Thus, Beach[3] reports a case of compound fracture and separation of the lower epiphysis of the humerus, with crushing of the ends of the radius and ulna, in a boy aged eight, who had been run over by a horse-car.

Such injuries involve almost of necessity the total loss of mobility of the elbow-joint, as well by reason of the damage to the soft parts apt to attend them, as by the irregularity of union of the fragments, and the obliteration of the joint-cavity by inflammation. Of course, if the vessels and nerves are torn, there is danger of gangrene, and amputation may be imperatively demanded. If, however, the vessels have escaped, the arm may be placed in such a position as to make it most useful, and the case treated with the expectation of ankylosis.

A much better result, however, can be attained, if the muscular and ligamentous tissues have not been destroyed, by the excision of the joint. Beach, in the case just cited, adopted this course, and his little patient made a perfect recovery, the arm being as useful as the other, although three inches shorter. The operation may be done as a primary procedure; but there are some advantages in waiting until a later period.

Fractures of the olecranon are very rare in children. The youngest case known was reported by Eames,[4] in a child only four years of age, who fell on the elbow. Hamilton records one in a boy aged seven, which occurred during the reduction of an old backward luxation of the elbow. He mentions one which had happened to a boy aged fourteen, and which he examined sixty-nine years later; the union seemed to have been bony.

In the Warren Museum[5] there is a specimen with the following history: a boy aged eight injured his elbow, and four or five years afterwards noticed something movable in the joint, which prevented its flexion; when he was twenty-three years old it was excised, and was supposed to be the detached olecranon.

Fletcher[1] met with a fracture of both olecranons, in a boy aged sixteen; upon his death less than a year after, bony union was found on each side.

Annandale,[2] in the case of a boy aged sixteen whose olecranon was fractured by the kick of a horse, found the fragment drawn up and united to the humerus; he laid open the parts, divided the triceps, and sutured the fragment to the body of the ulna, with good result.

The best position of the limb for treatment is with the elbow not straight, but nearly so,—say at an angle of about one hundred and thirty-five degrees,—so that the trochlea shall act as an aid to the splint; the fragment should be drawn down by strips of adhesive plaster properly applied.

Fractures of the coronoid process are claimed to have been observed in a number of cases. Hamilton doubts them all, but, as it seems to me, on insufficient grounds. Duer,[3] in the case of a boy aged six who had fallen from a hay-mow, could grasp the fragment between his thumb and finger.

Liston's case[4] has become classical, although the account is so wholly wanting in detail as to have no practical value. He says merely, "I saw a case lately in which the injury arose in consequence of the patient, a boy of eight years, having hung on for a long time from the top of a high wall by one hand, afraid to drop down."

One case presented itself to Hamilton, in which a boy nine years old had fallen, and had a backward luxation of the elbow, easily reduced, but recurring as easily; he formed and expressed the opinion that the coronoid process was broken off; but five months later, finding that the motions of the joint were perfect, and that "if the coronoid process had ever been broken it was now again in its natural position, and with every structure about it in a condition as complete as it was before the accident," he thought his view disproved.

Annandale[5] has reported a curious case, in which, excision of an elbow (luxated backward and rigidly fixed) being performed, the tip of the coronoid process was found broken off, drawn upward and inward, and attached by fibrous adhesions to "the *posterior* aspect of the inner condyle." The patient was a boy twelve years of age.

These four are the only instances recorded, so far as I know, in children.

It seems to me that this lesion should be classed among the "sprain-fractures." Between the forward push of the humerus and the upward pull of the brachialis anticus, the process is partly split off and partly torn off.

The symptoms need hardly be detailed, but the most important will be difficulty in voluntary flexion of the elbow, and the detection of the fragment.

As to treatment, the elbow should be flexed, and kept so by means of a suitable splint for three or four weeks at least. Extension should then be cautiously and gradually made.

Fractures of the forearm, involving both bones, are in children more commonly met with than those of any other part of the skeleton. Coulon says that of one hundred and forty fractures treated in one year at the Hôpital Ste.-Eugénie (Enfants Malades) thirty-eight, or over twenty-seven per cent., were of the forearm; and other authorities give nearly as large figures. The most frequently assigned cause is a fall on the hand. Humphry[1] saw one case, in a child, from convulsions in whooping-cough. Plunket[2] has reported a case in which a child was born with a fracture of the right forearm, apparently caused by the violent contractions of the mother's womb; but there was also talipes varus of the right foot, and the thumbs were flexed into the palms. The result was good.

Incomplete fracture, or bending of the bones, first thoroughly studied in this region, occurs much oftener here than elsewhere. Coulon gives seven cases observed by him, and quotes nine others from different sources. Occasionally one bone is broken through, and the other only partially so; I think in such cases it is always the radius in which the separation is complete.

Sometimes the two bones give way at the same level, but often the radius is broken higher up than the ulna. Not infrequently, however, the radius is fractured near the wrist, the ulna yielding at or about the middle. The mechanism of these fractures does not seem to need explanation.

Usually the symptoms are unmistakable. There is pain, helplessness of the limb, and deformity. This deformity generally consists in an angle more or less pronounced, and salient toward the dorsal aspect of the forearm; sometimes, however, the angle is in the opposite direction, the projection being on the palmar surface. If the fracture is complete, there is mobility and crepitus.

A good deal of bruising is apt to attend these injuries, especially toward the wrist, where there is no great thickness of soft parts; and sometimes the fragments seem very near penetrating the skin. Compound fractures of this part are not, however, common.

Along with the angle just mentioned, there is almost always a certain amount of twisting, due partly to the fracturing force, and partly to muscular action.

Union takes place readily in the majority of these cases. I have seen it firm on the fourteenth day, in a little girl three years of age.

---

[1] British Medical Journal, November 15, 1884.

[2] Nashville Journal of Medicine and Surgery, August, 1879.

Generally speaking, the great danger to be apprehended is the permanent disability of the member from union of the fragments in a faulty position. Hamilton, however, mentions an instance in which a boy aged ten, badly treated by an empiric, died of tetanus on the sixth day. And it must be borne in mind that gangrene has repeatedly caused the loss of a portion, or even of the whole, of the limb, by reason either of too tight bandaging or of interference with the vessels by the fragments. Of this Hamilton records five cases observed by himself.

When we examine the skeleton of the upper extremity, it is clear that the interosseous space in the forearm is widest when the hand is in a state of semi-pronation, with the thumb directly upward. Hence, in view of this fact only, this would be the best position to maintain in the cases now in question. But if the fracture of the radius is above the insertion of the pronator teres muscle, its upper portion will be rotated outward by the supinator brevis, as well as by the biceps; and if union takes place under these circumstances the extent of supination will be greatly limited. In such cases, therefore, the lower fragment should be made to follow the upper, by putting the whole forearm in complete supination, in which posture the interosseous space is nearly as wide as in semi-pronation.

With regard to the ulna no such precaution is needed, as it has only a hinge-motion at the elbow, and no rotation; and, being subcutaneous in its whole length, the accuracy of its line can be readily ascertained.

Upon being called to a child with fracture of the forearm, the surgeon's first duty is to determine the seat of the injury in each bone. The nearer the wrist it is, the greater the chance of damage to the vessels. Anæsthesia may be necessary to a thorough examination and reduction. If the fracture of the radius is below the insertion of the pronator teres, the fragments may be brought into proper relation by extension from the wrist, an assistant making counter-extension from the elbow. The sufficiency of the interosseous space can be determined by the surgeon passing his hand up and down, with the fingers on one side and the thumb on the other, the little patient's thumb being upward. The proper apposition of the fragments being thus assured, two splints are to be applied, one on the dorsal and the other on the palmar aspect of the forearm. The extension of the palmar splint up along the inner side of the upper arm, with an angle at the elbow, will effectually prevent rotation of the forearm; the palmar splint should also reach down as far as the ends of the fingers, so as to support the whole hand. The dorsal splint need only reach from the elbow to the wrist.

These splints should be of such width as fully to protect the forearm from the pressure of the turns of the bandage, which would otherwise tend to crowd the fragments together; but they should not be so wide as to allow of lateral displacement. It is not necessary to apply compresses to keep the bones apart, but my own practice is to make the raw cotton padding a little fuller along the middle.

Much care must be taken in putting on the bandage, lest, on the one hand, the fragments should not be duly controlled, or, on the other, there should be too much pressure. I consider the proper dressing of a fractured forearm in a child a somewhat severe test of surgical skill.

In the case of the radius being broken above the insertion of the pronator teres, the same precautions are to be taken, but, instead of the two splints, only one, an anterior angular one, is to be used.

Gayraud[1] has recorded the case of a girl twenty-eight months old who had had both forearms broken twenty months before; on the right side union had taken place with the fragments at a right angle "like a second elbow." On the left side the angle was much less marked. Straightening was accomplished, and the ultimate result was good.

Dunn[2] met with a case of incomplete fracture at about the middle of the forearm, in a girl two and a half years old; it was easily reduced, the radius giving way with a "crack," and recovery was complete in three weeks.

Robson[3] saw a boy six years old who when two years of age had been run over by a cart, and had probably sustained a fracture of both bones; he had had no treatment, but the only trace of the injury was a projection of the radius upward and inward just below its head; supination was impaired.

Canniff[4] says, "Recently I have had under my care an incomplete fracture of the radius, with compound fracture of the ulna, about two inches from the wrist-joint." The patient, a boy eight years old, had fallen on the ground on his hand.

Dr. H. R. Wharton informs me that he saw in 1888 a boy aged twelve who by a fall from a horse had sustained "a fracture of the lower end of the radius, with great deformity, the hand being markedly drawn inward, and the ulna being decidedly curved inward, the point of greatest curving being about two inches above the styloid process. In making pressure to reduce the deformity, the ulna gave way with a snap at the point above mentioned." Reduction was then easy, and the boy recovered, with "a very perfect arm."

I have recently had at the Pennsylvania Hospital a boy aged eight years who some months previously had sustained fracture of both bones of the right forearm about one inch above the wrist. Necrosis of the fragments followed, and I removed the end of the diaphysis of the ulna and part of that of the radius, leaving the epiphyses in place.

In cases where there is much bruising of the soft parts, and especially when penetration of the skin by the fragments has been threatened, it is much safer to apply lead-water and laudanum, or even evaporating lotions, with somewhat loose bandaging, until the parts are in a better condition to bear pressure. Of course the fragments are to be carefully adjusted in the first place; and the child will probably of itself avoid any motion, for fear of pain.

[2] Transactions of the Minnesota Medical Society, 1881.

[3] Lancet, March 21, 1885.

[4] Manual of Surgery, 1866, p. 293.

When the fracture is compound, it must be treated on the usual principles, the healing of the wounds being promoted by the most rigid antisepsis; the proper position of the bones being meanwhile maintained as accurately as possible. A good result can often be obtained in children under circumstances which in an adult would call for amputation.

Should a case present itself in which union has taken place with the fragments at an angle, an attempt should be made to correct the deformity by bending the callus, or by refracture if consolidation is complete. Or, if there has been rotary displacement, it may be justifiable to cut down and expose the fragments, and to suture them together in proper relation.

While maintaining in the fullest degree the statements already made as to the importance of careful and accurate treatment of fractures of the forearm, I would note, as a matter of curiosity, that Hamilton[1] mentions three cases of young children in which no dressings whatever were employed, yet in which the results obtained were perfect. He refers to another instance[2] in which a boy of ten years, after a fracture near the lower end of the forearm, had so great a deformity that refracture was seriously thought of by his attendant; gradually, however, the limb became straight, and eighteen years afterwards there was no trace of the injury.

Fractures of the radius alone may occur at any point, but, as in adults, are far more frequent close to the wrist. Stimson mentions a curious case in which, in a boy aged thirteen, the outer half of the head of the bone was separated by a blow from the runner of a sled; the diagnosis was verified upon excision of the joint, made necessary by suppurative arthritis. Foulerton[3] has reported the case of a boy nineteen months old, whose hand was pulled upon, with the result of fracturing the radius through its upper epiphysial line, and the clavicle at the junction of its middle and outer thirds.

Of fractures at any point in the length of the shaft, little need be said, as the condition of things is very similar to that in fractures of both bones.

A case is reported by Waitz[4] in which a boy aged fifteen fell from a scaffold, sustaining a compound fracture of the right radius, and a simple one of the left; on the sixth day there was difficulty of swallowing, and on the ninth death occurred from tetanus.

[3] Lancet, October 2, 1886.

[4] Report of Esmarch's Clinic, Archiv für Klinische Chirurgie, 1877, vol. xxi.

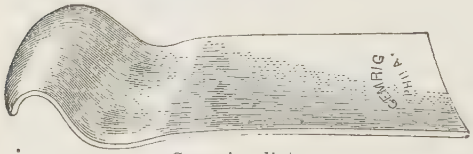
When the radius is broken near its lower extremity, it is almost invariably by a fall on the hand. These fractures are generally said to be infrequent in early life; but I recently had at the Pennsylvania Hospital, within forty-eight hours, four cases of Colles's fracture in patients between five and twelve years of age. All these were from simple ordinary falls on the hand; there was no ice (it was in October) or any other circumstance to account for the coincidence. I have repeatedly seen this injury on both sides, from falls from greater or less heights. In one case, many years ago, a boy about ten years old fell five stories, with no other damage; he made a good recovery.

Sometimes, no doubt, the portion separated is the epiphysis; but I think this is very rare. A case is quoted from Brunner[1] in which a boy aged fourteen had an injury of this kind, followed on the fourteenth day by tetanus; upon resection of the bulky callus, and freeing of the radial nerve, the symptoms disappeared. Butler[2] has recorded a curious case, in which a boy of fourteen, by a fall from a height of thirty feet, had the styloid process broken off and drawn upward an inch and a half, where it became firmly united.

The symptoms of fracture of the radius close to the wrist are very characteristic, especially in thin children. Just above the joint there is a more or less abrupt swelling on the dorsum, and on the palmar surface, corresponding to the fold of the joint, there is a deep transverse furrow. The hand is helpless, and generally strongly pronated. Crepitus is apt to be very readily elicited, and mobility of the fragments often exists. I have never seen in a child the impaction which so commonly attends these fractures in adults.

Reduction is generally not difficult, but the fragments readily slip out of place again. I think, therefore, that the treatment of these cases in children should differ from that in adults, in whom the fracture, once fully reduced, is apt to remain so. I think the Coover splint (Fig. 16) the best for the purpose of giving the parts perfect support in a comfortable position. It is very important to select the proper size. Should this splint not be at hand, a very good substitute can be made by cutting out a thin piece of wood of the shape of the forearm and hand, and then fastening a block of wood on it so as to fill up the concavity of the under surface of the forearm near the wrist; this block should be thicker at its radial side,

Fig. 16.



Coover's splint.

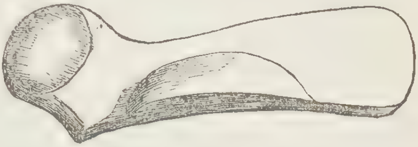
---

[1] London Medical Recorder, July 15, 1886.

[2] New York Medical Journal, November, 1857.

and slope off toward its ulnar margin (Fig. 17). A small semi-oval block should be glued or nailed on to correspond to the hollow of the hand. This splint, it will be seen, resembles somewhat the "Bond" splint, which, however, is usually made with a total disregard to anatomy, and the employment of which has left many a misshapen wrist.

Fig. 17.

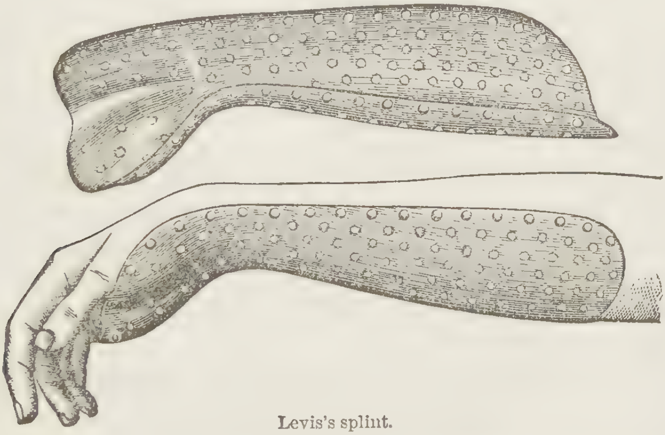


Splint for fracture near lower end of radius.

Levis's splint (Fig. 18) would answer very well, the small size being employed.

Thorough reduction having been made, the splint, properly padded with raw cotton or with a double layer of canton flannel, is applied, and secured by means of a bandage. In the case of restless or unruly children one or two wide strips of rubber adhesive plaster may be cast around the splint and the forearm before putting on the bandage. The hand should be supported by a sling.

Fig. 18.



Levis's splint.

Nearly all American surgeons use some form of palmar splint in these fractures. But if circumstances prevent the procuring or making of such an appliance, a straight splint may be adapted to the back of the forearm and hand, and will answer a very good purpose, at least as a temporary resource.

Fractures of the ulna alone are very rare in children. Bellamy[1] has reported one in the upper third of the bone from a fall on the hand, in a child six years of age. In the museum of the Pennsylvania Hospital there is a specimen of double fracture of the ulna, from a boy aged fifteen, the forearm having been bent around a revolving shaft. "The upper fracture is near the junction of the upper and middle thirds, and is somewhat oblique. The lower fracture is in the lower third, and is transverse. At the time of removal the fractures were not complete, the fibres of the bone which remained unbroken being much bent."

---

[1] British Medical Journal, September 16, 1876.

Pain, swelling, and tenderness and crepitus at a certain point, will indicate the character of the injury.

The treatment should be the same as for fractures of both bones at or below the middle.

It should be remembered that fractures of the ulna may be seriously complicated by other injuries. Hamilton gives two instances in boys aged nine, in which the ulna was broken, and the head of the radius dislocated forward. Careful examination of the whole limb should, therefore, be instituted in every case, for the surgeon's credit as well as for the patient's advantage.

Fractures of the carpal bones and of the bones of the hand are extremely rare in children, except as the result of direct violence, and then the injury is apt to be compound. I have reported[1] the case of a boy aged three years, who two years before had had the first phalanx of the thumb broken by the fall of a heavy lid upon it, with non-union; by scoring the apposed surfaces of the fragments, and very careful splinting, consolidation was effected.

When in young subjects compound fractures occur in this region, the surgeon will do well to remember that nature sometimes exceeds our expectations; and even when the injury seems to be beyond repair, it may in a few days, under rigid antisepsis, assume a more hopeful aspect. Perhaps, at least, the amount of inevitable sacrifice by amputation may be found to be less than was at first supposed.

FRACTURES OF THE BONES OF THE LOWER EXTREMITY.—**Fractures of the femur** are, according to all authorities, among those most commonly met with in early life. The bone may give way at any point, but in the great majority of cases the shaft is the part affected.

Intra-uterine fractures of this bone have been recorded. Hofmokl[2] saw a case in which union had already taken place, and quotes another from Wagner; he also mentions a case of Schubert's in which the fracture was compound.

I have myself known of several instances in which, during the delivery of a child presenting by the breech, the femur has given way under the pressure of the blunt hook. Powerful expulsive contractions may produce the same effect, as in a case recently reported.[3] I may anticipate the discussion of treatment by saying that here the attendant thought "that the most natural position would be that which had been in utero—doubled up on the abdomen," and treated it accordingly, applying a second binder with an opening through which the leg and foot were passed: at the third week, when the report was made, there was "considerable firmness, very good position, though of course a good deal of thickening."

---

[1] American Journal of the Medical Sciences, July, 1875.

[2] Archiv für Kinderheilkunde, 1882.

[3] Lancet, March 5, 1887, communication signed "Æ."

Separation of the upper epiphysis, the head of the bone, has been diagnosed more or less positively in a number of instances, and has once been proved beyond doubt by dissection, in a boy aged fifteen,[1] run over by a wagon. Sir Charles Bell[2] states that he has seen it result "from a fretful child casting himself backward while held in the nurse's arms," but in the entire absence of detail the case is without value. Hamilton mentions one instance in his own practice, in a boy fifteen years old; he quotes one from Parker which had happened to a girl of eleven, seen seven years later, and one from Wardner in a boy of fourteen. South[3] had a case in a boy aged ten, suspected to be of this character; the boy fell from a first-floor window upon the hip. Coulon's case, in which the neck of the femur gave way during the straightening of a diseased hip, although the force used was so gentle that the child did not cry, may have been a separation of the epiphysis. Barton[4] has reported an instance in which this injury was suspected, in a boy aged fifteen; but it seems likely that there had been previously a pathological condition of the bone or of the joint, as the patient had limped for some weeks. Robson[5] saw a girl aged five, who had four years before fallen heavily upon her side; no treatment had been instituted; the foot was everted, and the limb shortened, measurements showing that the loss of length was above the trochanters. (If the statement of Sappey, that the upper epiphysis of the femur appears at the beginning of the second year, is correct, the probability is that the lesion here was of a different character from that now under consideration.)

I have now in my ward at the Pennsylvania Hospital a boy fourteen years old, who is just recovering from an injury of the left hip, which I believe to have been a separation of the epiphysis; he was knocked down in a scuffle, striking on the hip.

The symptoms of separation of this epiphysis would not vary materially from those of fracture of the cervix femoris in adults,—shortening of the limb, eversion of the foot, crepitus and undue mobility, pain, and usually loss of power. All these were present in my case just mentioned. South's patient "suffered so little inconvenience that he had two or three times got out of bed and walked about for a short distance;" and Wardner's, for twenty-four days, had only "a lameness in the hip-joint and some difficulty in walking."

As to treatment, absolute rest and moderate extension are the essentials, and should be maintained for three or four weeks at least, the condition of the part being then cautiously tested, and the extension continued if there is found to be a tendency to renewal of the shortening.

[5] Lancet, August 21, 1886.

Extra-capsular fracture of the *neck of the femur* is said by Lee[1] to have been seen by him in a boy aged ten; but no details of the case are given. Sir A. Cooper cites a case under the care of Mr. Gwynne, in which a boy aged fourteen had a dorsal luxation of the femur of a month's standing, in attempting to reduce which, by extension with pulleys, the neck of the bone gave way. This may have been a separation of the epiphysis, but under the circumstances it is quite possible that there was an extra-capsular fracture of the form commonly met with in adults. A good deal of strength in the limb was ultimately acquired. Leisrink[2] mentions the case of a boy aged seventeen who had a dorsal luxation of the femur, of six months' standing; in the attempt at reduction, the bone gave way close to the trochanters, "evidently within the capsule;" consolidation took place in thirty-five days, with two inches shortening; the luxation probably remained unreduced, but it is not so stated. Allis[3] has reported a case in which in a child eighteen months old there was found after death "a fracture of the neck of the right femur, with loss of substance." There were other injuries, to be hereafter mentioned, and an obscure history of traumatism, besides some evidences of rachitis.

Separation of the epiphysis of the *greater trochanter* is recorded by Sir A. Cooper as having been observed by Mr. Key in a girl aged sixteen, who had fallen on a curbstone, striking her hip; the diagnosis was verified by an autopsy. Bryant mentions a similar case in a boy aged twelve, under Mr. Poland's care. McCarthy[4] reports that a girl eight years old, having fallen on her left side, had an abscess in the hip, and this extended into the pelvis; pyæmia, with pericarditis, pleurisy, and pneumonia, ensued, and after death the trochanter was found detached. Roddick[5] saw, in a boy aged sixteen, an abscess of the hip, from which the necrosed trochanter was removed; it had been separated apparently by a muscular strain during exercise.[6]

When this fracture occurs, the trochanter may be entirely drawn away, and it will be missed from its proper place. If still attached, it will be movable, with crepitus. In the former case very little can be done in the way of treatment; in the latter, fixation of the fragment may be effected by means of adhesive strips carefully adjusted.

Fractures of the shaft of the femur are for convenience divided into those of the upper, middle, and lower thirds. In children, as in adults, those of the middle third are much the most common of all.

[4] Transactions of the Pathological Society of London, 1874, vol. xxv.

[5] Canada Medical and Surgical Journal, November, 1875.

[6] In the Museum of the New York Hospital (Catalogue, p. 87) there is a specimen showing fracture of the femur through the line of junction of the neck of the bone with the shaft; a portion of the greater trochanter is also broken off. It was taken from the body of a girl aged nine, who had fallen out of a window.

Either direct or indirect violence may cause this bone to give way. In the latter case there is very often a twist impressed upon the bone, as well as the force at either end. A most extraordinary case is mentioned by Fayrer, in which a boy only thirty-four days old sustained a simple fracture of this bone by the bite of a jackal; union was complete in three weeks. A very few instances are on record in which muscular action has been alleged as the fracturing agent. One is the now classical case of Poupée-Desportes, in which a negro boy, in convulsions, broke both femora in their upper thirds. Another, quoted by Gurlt from Schröder, was that of a rachitic girl five years old, who for the fourth time in two years broke both femora while in a convulsion. A third, in a boy aged twelve, was reported by Lente;[1] an interval of eight months, however, elapsed between the two fractures, the second of which was still ununited when the boy died six weeks afterwards. Beck[2] has recorded an instance in which a boy six and a half years old was lifting another boy on his back, when his right femur gave way a hand's breadth above the knee.

"Spontaneous" fracture of the femur has been reported by Rankine.[3] A child aged six years "was simply walking across the floor, when its leg doubled up, the child falling instantly to that side." The femur was found to be broken in its middle third. The mother declared positively "that she was looking at the child walking over the floor at the time, and that there was no stumbling or anything, but only the leg seemed to double by the mere act of walking. It may be mentioned that the child did not seem to be in the best of health, although nothing very particular could be detected about it." In another case, reported by Cribb,[4] a boy aged eight had had coxalgia and abscesses in the right hip for four years; his left femur gave way at the junction of the middle and lower thirds as he turned in his carriage; union took place slowly but firmly.

The symptoms of fracture of the shaft of the femur are usually unmistakable. Walking is impossible; the limb is deformed, and usually curved by reason of the thickness of the soft parts, the convexity being, as a general rule, outward. In fractures in the upper third of the bone, the upper fragment is apt to be tilted upward by the action of the iliacus and psoas muscles. Of this Detmold[5] relates an instance in a child six years old. Here the convexity is forward, and the want of purchase on the short upper fragment makes it necessary to carry the lower one up after it, as it cannot be kept down. On handling, there is mobility at the seat of fracture, and more or less distinct crepitus.

For the most part, union takes place rapidly in these cases. Coulon gives nineteen uncomplicated cases, of ages ranging from two to ten years, in which the average duration of treatment was almost exactly sixteen days. The shortest period was ten days, the child being two years old, and the longest thirty, the child being two and a half. My own experience would lead me to assign a longer time, say twenty days, as a safer limit. I think that after all restraint is removed from the limb the child should be kept in bed for a week before being allowed to try to walk. Coulon mentions the case of a scrofulous boy aged seven, who had coxalgia; he fell out of bed and fractured the femur; extension being impossible, the limb was placed on a double inclined plane, and in eight days "there was a very solid callus."

Some swelling of the knee, from effusion into the joint, is apt to occur within a few days. I have never seen it persist after the uniting of the fracture, and generally it disappears in a much shorter time.

Fayrer[1] mentions a very rare case: a Mohammedan boy aged twelve died of erysipelas supervening upon a simple fracture of the femur in its lower third.

Shortening, which is so apt to give rise to permanent lameness in adults, can generally be easily obviated in children, as the resistance to extension in them is so much less. Indeed, excellent results are often obtained without extension by special means. Unless in exceptional cases, there ought not to be an appreciable degree of shortening; and what there is may be expected either to be obviated by compensation, or to disappear with the process of growth.[2] Gross[3] records an instance in which an infant four weeks old was brought to him "on account of a fracture of the shaft of the right femur, caused two days previously by a child rolling over it in bed. The thigh was much swollen, and at least an inch and a half shorter than the sound one; all the extension and counter-extension that I could make with my hands failed to restore it to its normal length."

As to the treatment, there have been very great diversities of practice. We have the example of Paget and Callender[4] as a warrant for dispensing with all apparatus; "the child being laid on a firm bed, with the broken limb, after setting it, bent at the hip and knee, and laid on its outer side."

By others, notably by the late Dr. Sands,[5] of New York, plaster-of-Paris bandages have been warmly advocated. Bell[6] has spoken in strong terms of the advantages of this method. My own experience with it has been very favorable; but it needs to be carefully watched, lest, on the one hand, the compression exerted should be too severe, or, on the other, with the subsidence of swelling, there should be too little control of the fragments. Hamilton was much opposed to it, and relates the case of a boy aged four in whom gangrene followed its use; but it seems to me that the bad result was due not to the method, but to inexcusable neglect on the part of the surgeon in charge. Mason[1] reports the case of a boy aged three, with a fracture in the upper third of the bone, successfully treated by this plan, the silicate of sodium, however, being substituted for plaster of Paris. I have myself employed silicate of potassium with great satisfaction, the advantage of it being that it solidifies very rapidly. Of the other materials used in solidifying dressings, glue, paraffin, starch, etc., it is needless to speak here, as the principle involved is the same in all.

Extension in some form is very generally used in fractures of the femur in children. Most of our cases at the Pennsylvania Hospital are put up like those in adults, with a proportionate weight attached by a cord passing over a pulley at the foot of the bed, for the purpose of making continuous extension. This cord is fastened to a bit of thin board about two inches square, placed in the middle of a strip of adhesive plaster, the ends of which are carried up along each side of the leg as far as the seat of fracture, and confined by strips or by a roller. Sand-bags of suitable size are placed at either side of the limb to steady it. When there is a tendency to angulation of the thigh, a splint of sheet-zinc or of binder's board is carefully moulded to the part, and bound on.

Hamilton recommends a sort of box, consisting of two long splints, one on each side, extending from the axillæ to beyond the soles, where they are connected by a foot-piece; this latter is so long as to keep the feet widely separated. Coaptation-splints of binder's board are applied to the injured thigh, and the leg is bound to the corresponding long splint with a roller. The remainder of the limb, the opposite limb, and the body are made fast with broad and separate strips.

[1] Medical Gazette, January 10, 1880.

Vertical extension, as advocated by Kümmel,[1] I have never employed. Lenze,[2] reporting a case of its use in a boy aged two, commends the plan on account of its cleanliness; he says he received it orally from Schede, and did not know with whom it originated. A curious effect of this treatment has been observed in female children,—viz., vaginal catarrh; it is said to yield promptly to appropriate measures as soon as the extension is discontinued.

Smith's well-known anterior wire frame is reported by Wright[3] to have been used with good result in a case of fracture somewhat above the middle of the bone, in a child five years old. This method might answer well in those troublesome cases where the fracture is near the trochanters and it is impossible to prevent tilting up of the upper fragment. Perhaps the same should be said of vertical extension.

Whatever plan of treatment may be adopted, children with fracture of the femur cannot be prevented from wetting the bed, unless care is taken to protect it. Perhaps the best way to do this is to have a thin square pad of absorbent material, with oiled silk or rubber cloth beneath it, properly placed to receive the urine, and changed as often as it becomes soiled. Even the most constant watchfulness can hardly anticipate every action of the bladder.

As to the fæcal discharges, they should be received in a bedpan warmed and very carefully placed under the child, the sound limb being raised for the purpose. Children above the age of mere infancy can be soon taught to give notice of their desire to have a movement.

A case of fracture of both femora, one compound, in a boy aged six years, has been reported by Peter.[4] Desault's apparatus was used on each (a long outer splint, reaching from the iliac crest to beyond the sole, and an inner one from the perineum to the ankle); union took place in twenty-nine days, and on the forty-third day the boy was walking out.

Union is sometimes very slow in occurring. In one case, reported by Poinsot,[5] a boy aged ten had a fracture just below the trochanters, which did not consolidate for six months; the delay was ascribed to "local scurvy." Lyford[6] was called upon to treat a boy who had broken his thigh at the middle eleven months before; blisters having failed, a seton was passed, and after forty days of treatment the bone became firm. Marks[7] has recorded the case of a girl aged fourteen who at the age of two and a half years had a fracture of the femur at two points; it did not unite for six months, when a fragment was removed from the lower portion; the muscles shrank, and the knee became stiff. At thirteen years and seven months, the bone was again broken at the junction of the middle and lower thirds; plaster of Paris was applied for three months, and then the fractured ends were rubbed upon one another; the plaster was reapplied, and she got up upon crutches; union was finally obtained with one and one-fourth inches shortening.

[7] Journal of the American Medical Association, November 6, 1886.

When union takes place with great deformity, operative interference may be called for. Clémot,[1] in the case of an infant only forty days old, with the left thigh united at an angle of about one hundred and twelve degrees, from what was supposed to be an intra-uterine fracture, tried extension for three months; this failing, he cut down upon the bone and divided it with a chain-saw; union ensued with a straight but considerably shortened limb. Wasserfuhr in 1816 [2] successfully resected the femur of a child aged five years, for union of a fracture above the middle, the fragments being at an angle of nearly ninety degrees. Langenbeck records a similar operation performed by him on a girl aged three, with a fatal result on the eighth day, caused, as he supposed, by carbolic-acid-poisoning.

Refracture has been resorted to with success in many instances. Buck[3] reported a case, in a boy aged five, in which four operations were required at intervals of four weeks; union was at last obtained with very little (one-fourth inch) shortening. Fayrer[4] got a good result in two cases, an English boy aged fourteen, and a Hindoo boy aged ten. Heath[5] has recorded two, in boys aged seven and twelve respectively.

In 1882 a child three years old was brought to me with a very great deformity from an old fracture of the femur just below the trochanters, union having taken place with an outward angle of about ninety degrees. The lameness was very like that of hip-joint disease. The child had been allowed to walk while the callus was yet plastic, and the lower fragment had tilted up the distal end of the upper. Not being then a believer in antiseptic surgery, I declined to attempt interference; refracture was out of the question, the upper fragment affording no purchase.

In 1879 I refractured the femur of a boy aged twelve, who had sustained a very severe fracture nearly three months before by his leg being entangled in a carriage-wheel, and who had been ignorantly treated in the country; the deformity, which was very great, was completely corrected.

When necrosis affects the femur, it sometimes happens that the shell of new bone breaks. An instance of this kind came under my notice in the Pennsylvania Hospital, in a boy aged thirteen, from whose thigh I had removed an enormous sequestrum some time before; union took place very readily. Thompson[1] has reported a case in which the fracture took place very near the knee, in a boy aged nine, who died from hemorrhage, the artery having been wounded by the sharp upper fragment. A very similar case, in a boy aged sixteen, whose life was saved by amputation, has been reported by Brooke.[2] In the Warren Museum[3] there is a specimen from a case in which a boy aged fifteen jumped from a wall, injuring the femur so that inflammation and necrosis followed, and the bone was broken, uniting with a shortening of three or four inches; repeated attacks of inflammation ensued, and the knee-joint became involved, so that twelve years later amputation was performed with a good result.

Compound fractures of the femur are very rare in children; they are to be treated on the same principles as in adults, but, as in other parts of the body, the youth of the patients affords more chance for successful conservative surgery. Amputation is sometimes demanded. McFarlane,[4] in the case of a little girl aged two, who was run over by a wagon, removed the limb at the hip-joint; and the child, after passing through a severe attack of bronchitis with diarrhœa, was discharged cured on the thirty-eighth day.

Fisher,[5] in 1803, in a boy aged nine, resected three inches from the lower fragment of a femur broken at its upper part; the fracture was compound, and no union had taken place; in less than two months consolidation occurred, and a complete recovery ensued, but with the limb shortened.

Fractures at the lower end of the femur have been recorded as occurring to children in a few instances.

Sir A. Cooper relates the case of a boy who had his leg entangled in a wheel and sustained a transverse fracture, with separation of the external condyle, which exfoliated; ankylosis was expected, and the limb was dressed in the straight posture, but five months after the accident the boy walked well, with free use of the joint.

Langenbeck treated a boy aged six who by a fall had a T-fracture of the condyles, the knee-joint being full of blood; yet recovery took place with almost normal movements, and no shortening. Hamilton records the case of a boy aged seven who in jumping down about three feet broke the femur obliquely downward and backward just above the knee; the limb was placed on a double inclined plane; gangrene of the foot ensued, but the fracture united well, with fair motion of the knee. The gangrene was supposed to be due to pressure upon the artery by the end of the upper fragment.

A case of separation of the inner condyle of a boy aged fifteen, by the kick of a horse, was reported to Hamilton by Riggs; the whole leg, with the fragment, was displaced upward and inward, reduction being accomplished with much difficulty; but a good recovery ensued.

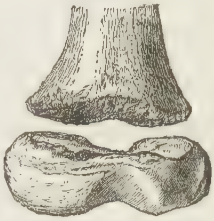
Separation of the *lower epiphysis of the femur* is a very grave accident, but more frequent than disjunction of any other epiphysis, nearly fifty instances being on record.[1] Allis has reported[2] a case in which there was a complete separation in one limb and a partial one in the other; the child, who was about eighteen months old, and presented some signs of rachitis, was supposed to have been hurt, about two weeks before its death, by an older one sitting on its legs.

With regard to a number of the cases the details given are very scanty. The diagnosis can be positively made only when the injury is compound, or when amputation of the limb or the death of the patient affords an opportunity for the dissection of the parts. Very great violence is necessary to produce this lesion. A curiously frequent cause of it has been the entanglement of the limb in the wheel of a moving vehicle; twenty-four such cases have been published, and one has recently been under my own care. Several of the patients had their limbs caught in ropes, or in machinery; one fell a distance of eighty feet. The mechanism of it would seem to be over-extension of the knee, with more or less twisting and traction upon the leg.

Fig. 20.



Separation of the epiphysis of the femur. (Bryant.)

Such accidents would seem very unlikely to happen to girls, yet there are five among the subjects of the records.

When this injury is compound, the wound is generally at the back or inner side of the limb; in one case it is stated that the end of the shaft protruded forward.

My own case was a strikingly illustrative one. A boy aged nine was hanging on at the back of a wagon, when his leg was caught in the wheel. A large wound existed at the lower and back part of the thigh, and through this the end of the diaphysis, stripped of periosteum, protruded; the condyles were still in contact with the head of the tibia, but only by an edge, the whole epiphysis being rotated so that the articular face looked forward (upward) and the detached surface backward (downward); this was subsequently found to be due to the two heads of the gastrocnemius muscle. Ether was given, and a careful examination showed that, although there was very severe laceration and bruising of the soft parts, the vessels and nerve had not been torn, but had been pushed aside around the end of the shaft; they were, however, much stretched, and the blood in the artery was coagulated. Reduction was impossible, and an attempt to save the limb by resection seemed likely to be attended with such risks, that amputation was at once performed. The boy made an excellent recovery.

---

[1] Madame Lachapelle is quoted by Malgaigne and others as having seen this lesion produced in birth, by traction on the child's foot, the upper epiphysis of the tibia being also separated. But, as she says (Pratique des Accouchemens, tome ii. p. 225) that the limb was "altered by putrefaction," it does not seem to me that this case ought to be taken into the account any more than if the bones had been artificially macerated.

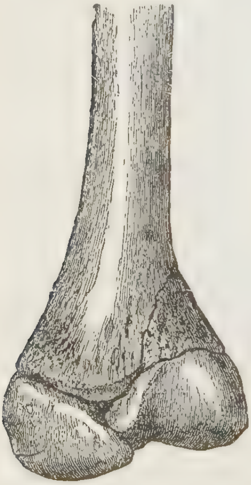
[2] Transactions of the Pathological Society of Philadelphia, 1878, vol. viii. p. 7.

The periosteum has been noted as stripped up from the shaft in almost every instance. Seven times the tilting of the epiphysial fragment, above mentioned, has been observed.

Primary amputation was performed in eleven of the compound cases, with four recoveries, three deaths, and in four the result not stated. Secondary amputation was resorted to in ten, with five recoveries, and in five the result not stated. In three cases, and probably in two others, the amputations were intermediate, with one recovery, one death, and three results not stated. Resection was resorted to in seven cases, four compound and three simple; two of the latter were amputated later, and belong in the preceding list also. In the other five good results were obtained. In five cases, three of which were compound, reduction was effected with success; some doubt may exist as to the diagnosis in the two which were simple. Details are wanting as to seven cases; two of these, however, were museum specimens, and in one the diagnosis was verified by amputation.

Secondary amputation was performed in one case on the thirteenth day, for hemorrhage; in one after three months, for stretching of the nerve by the end of the shaft; in one case after several years, for aneurism; in two for abscess, in three for gangrene, and in the other two for reasons not stated.

FIG. 21.



Separation of the lower epiphysis of the femur, with fracture. (Holmes's System of Surgery.)

Sometimes the separated epiphysis is itself broken into two or more fragments; this condition is represented in Fig. 21, which also shows (at the right) a small portion of the shaft detached along with the epiphysis. This, as already stated, has been frequently observed.

As to treatment, enough has been said to show that it must vary with the circumstances presented by each case. Reduction should, of course, be tried, if the damage to the soft parts has not been such as to forbid an attempt to save the limb; to effect it, the end of the diaphysis may have to be sawn off. When there is a wound, and the shaft projects through it, this is readily done; but if the skin is unbroken, an incision may be made for the purpose, as the additional risk involved in so doing would be small as compared with that of leaving the bone to itself. The displacement being corrected, a dressing such as that employed for any like case of fracture of the thigh should be applied.

The question of amputation is, of course, a very grave one, and involves points which can be settled only by consideration of the circumstances in each individual case.

(I have abstained from quoting the reported cases of this injury, because there were no special points to be illustrated by them without extending the discussion beyond the space available to me.)

Fractures of the patella are extremely rare in children, the bone scarcely existing as such in them. Malgaigne's youngest case was that of a boy aged eleven ; no particulars of it are given, but, from the fact that it was treated with his hooks, we may infer that it was transverse. Guersant[1] makes the vague statement that he had seen "only three or four" in his practice at the Hôpital de l'Enfant Jésus ; but in the utter absence of details this is open to some doubt.

Hamilton says that he saw a small piece of the margin of the bone broken off by a direct blow, in a boy aged five ; and S. Ashhurst[2] has reported the case of a girl aged four who, by falling on a marble, split the bone down vertically, near its upper and outer edge.

Fractures of the bones of the leg are comparatively infrequent in early life, although in a number of instances they have occurred to children within the womb. Malgaigne, among five hundred and fifteen cases, found but one as young as four years, and but twelve between five and fifteen years. Beck's tables[3] show, out of two hundred and forty-seven cases of fracture in children, but twenty-five, or ten per cent., in the leg, as against ninety, or about thirty-six per cent., in the thigh.

The tibia alone suffers oftener than both bones ; fracture of the fibula alone is exceedingly rare. The seat of fracture, in a large majority of the cases, is in the middle third of the leg. Direct violence from falls or blows would seem to be the most frequent cause, although, of course, the exact facts can seldom be obtained, even from grown-up witnesses of an accident. D. P. Smith[4] saw a case in which a boy aged six sustained a fracture of both bones by the leg being caught in the wheel of a carriage. When the violence is indirect, it is probable that there is in addition to leverage a twist of the limb. In either case the obliquity of the line of fracture is, as a rule, much less than it generally is in adults.

Partial or incomplete fractures of the leg have been recorded. Thore[5] quotes cases observed by Campaignac, Fleury, and Voillemier, the diagnosis in the two former being verified by dissection. Another case, in a boy aged six, has been reported by Gray ;[6] there was no crepitus, but the leg was deformed, straightening, however, in ten days under the pressure of splints. Bryant has figured a curious case in which a girl aged twelve had had a green-stick fracture united at an angle, and this angle filled up by a deposit of new bone, so that the antero-posterior diameter was six inches.

Fracture from necrosis has been recorded by Fayrer;[1] an English boy aged three and a half years had necrosis of the shaft of the tibia, and a sequestrum was removed; some months after, while healing was progressing, he fell and broke the new bone; union took place, but rather slowly.

As to the treatment of fractures of the leg in children, my own practice has always been to employ splints of binder's board, one on either side of the leg; they should extend from close to the knee to the foot, supporting the latter so that it cannot rotate. They should be well softened in hot water, and carefully moulded to the limb; they are then lined with an even layer of raw cotton, and bound on with a roller bandage. I have never seen a case in a child in which there was any difficulty in reduction. The inner edge of the patella, the inner malleolus, and the inner edge of the great toe should be in a line with one another.

Zinc or tin splints may be used in the same way. Some surgeons employ the immovable apparatus, with plaster, paraffin, or glue, from the first; but I think removable splints preferable. Care should be taken not to bind the limb too closely, lest the circulation be interfered with, as in Fleury's case above referred to, in one recorded by Holmes,[2] and in another reported by Krackowizer.[3] On the other hand, the apparatus must be so closely applied as to give perfect support and to prevent motion of the fragments.

There is good authority for the use of the "fracture-box" in children, but it necessitates their lying still, which they cannot always be made to do.

Suspension is needless in the case of very young children, but in older ones it may be made as in adults. My own method[4] of doing this has always seemed to me the most satisfactory.

As in the case of other bones in early life, union generally takes place very readily, and without permanent deformity. But it must not be taken for granted, because the child is comfortable, that all is well. On the contrary, in several instances which have come under my own notice, the limb has been in bad shape, although the little patient made no complaint whatever. And after the bone seems to be solidly united, care should be taken lest by the too early use of the limb the callus should yield, and a serious deformity result.

In the Warren Museum[5] there are three specimens singularly illustrative of the effects of neglect in fractures of the leg in early life. The bones tend to form an angle salient forward, and the lower fragments are crowded down close to the foot. In two of the cases firm bony union failed to occur, and in one amputation was finally resorted to. Watson[6] had to adopt a like course in the case of a boy aged fourteen, who when six years old had fractured his left leg, union taking place with the lower part bent inward and backward at nearly a right angle; after exsection of a wedge from each bone by Stevens, the limb was straightened, but union failed to occur, and the skin gave way.

Better results are sometimes attained, especially since the introduction of antiseptic methods. Beck[1] records the case of a girl aged ten months who had had an intra-uterine fracture of the leg, united at a right angle; osteotomy was performed, with success. Coote[2] reports the case of a boy aged eight whose leg had been misshapen at birth, in consequence, as was supposed, of intra-uterine fracture; it was refractured at about three years, but union failed to occur; in his sixth year ivory pegs were introduced, but without success, as the pegs dropped out during an access of fever; the limb was, therefore, removed, and the lower fragment was found to be atrophied. Jones,[3] in the case of a boy aged sixteen, who at five years of age had sustained a Pott's fracture, excised the inner malleolus and upper surface of the astragalus, corrected the deformity, and effected a cure with a movable joint. I have myself chiselled away a wedge from the tibia, united with an angle salient inward, in a boy aged fifteen, with good result.

Union sometimes fails to occur. I have at present under my care at the Pennsylvania Hospital a girl only thirteen months old, with pseudarthrosis of both bones about one and a half inches above the ankle; the history, which is very obscure, is that the child was in some way caught under a street-car about six weeks ago; a small sinus probably communicates with the false joint. Waitz[4] records a case of non-union of both bones in a boy aged two and a half years, treated by the rubbing of the ends together, and the application of a plaster bandage; a cure was effected at the end of three months. Mott[5] gives an account of a girl who had an ununited fracture of both bones, dating from intra-uterine life; various means were tried during her first year, and at last a seton was employed, which seemed to be succeeding, when diffuse inflammation came on, and the uniting material was dissolved. In a note it is stated that resection was performed at the age of eleven years; but the final result is not given. Hamilton saw a girl aged seven who two years previously had had a fracture (probably green-stick) of the leg below the middle; it united at an angle, and six months later was broken over again by a surgeon, but no bony union ensued.

Whitman[6] has reported the case of a girl who at the age of three years underwent osteoclasis for deformity of the legs and arms; there was non-union in the left leg, which was finally overcome by resection and wiring, with an excellent result.

[1] Jahrbuch für Kinderheilkunde, 1886.

[2] Lancet, June 21, 1862.

[3] British Medical Journal, March 13, 1886.

[4] Report of Esmarch's Clinic, Langenbeck's Archiv, 1877.

[5] Transactions of the New York Academy of Medicine, 1857, vol. i. p. 82.

[6] Medical News, April 14, 1882.

A curious case is recorded by Hamilton, in which a boy aged four had a compound fracture of his leg near the middle; an ulcer remained at that point, with frequent discharges of small scales of bone, for twenty-two years, when it closed, and he began to lose the use of both lower extremities. Probably the fracture had nothing to do with the paralysis.

So far, reference has been had to fractures of the shafts of the bones of the leg. Malgaigne mentions briefly the singular case of a girl aged eight, who had the inner malleolus fractured by the kick of a horse. Beaney[1] saw a fracture of the outer malleolus in a girl aged five and a half, who fell in running. I have myself seen a case of Pott's fracture in a girl aged fourteen, who had jumped from a third-story window; from culpable neglect on the part of the surgeon, a most deplorable deformity had ensued.

Separation of the epiphyses has been noted in a number of instances. Ashhurst[2] has figured such a lesion at the upper end of the tibia, from a boy aged eleven, in whom amputation was rendered necessary by railway crush. Heuston,[3] in the case of a boy aged eight, saw this accident followed by acute synovitis of the knee-joint, and seven months later by suppuration, which was successfully treated by erasion, and drainage through the popliteal space. Stimson says that Verneuil "saw the epiphysis separated in a child six years old, whose leg had been caught between the spokes of a wheel; the joint was not opened."

Separation of the *lower* epiphysis of the tibia has been figured by Holmes,[4] who quotes another case from R. W. Smith. Martin[5] has reported a case of compound disjunction of the lower epiphysis of the tibia, with fracture of the fibula about four inches above, in a boy aged eleven, who recovered perfectly in two months. A very similar case, in a boy aged thirteen, has been recorded by Albec,[6] and another, requiring resection, by Clark,[7] who refers to sixteen other instances. In Holmes's specimen above mentioned the lower epiphysis of the femur and that of the fibula are also separated; and the shaft of the tibia is broken below the middle; the patient, a boy aged eighteen, was caught in a coil of rope, and the injury was such as to demand amputation. Voss,[8] in a case of compound separation of the lower epiphysis of the tibia, succeeded in reducing the protruding end of the shaft; but a portion of the epiphysis became necrosed and was removed; the patient, a boy aged fourteen, recovered with a useful joint. Krackowizer[1] has reported a case of supposed traumatic separation of the lower epiphysis of the tibia, in a boy aged five; but, as the limb became gangrenous from tight bandaging, it seems possible that this may have had something to do with the lesion of the bone, which was only detected after amputation.

[8] New York Journal of Medicine, November, 1865.

The upper epiphysis of the fibula is reported by Stimson[2] to have been torn off in a child two years old, with fracture of the shaft of the bone, in a street-car accident.

Arrest of growth of the bone has been mentioned and figured by Bryant as having followed a separation of the upper epiphysis of the tibia in a child aged eight; the fibula grew normally, and was, therefore, bowed outward.

Compound fractures of the leg are rarely seen in children. Gooch,[3] in a very extensive injury of this kind in a boy aged twelve, sawed off about five inches of the tibia (about nine inches protruding), and obtained an excellent result, the bone being reproduced. In another case, that of a boy aged eight, seen by him on the fifth day, the fractured end of the tibia had protruded through a small wound; emphysema had begun in the leg and extended up to the abdomen, and death ensued two days later. Norris[4] removed two inches of the tibia in the case of a boy aged twelve, "notwithstanding which he was discharged cured in eleven weeks, with shortening of the limb of but half an inch, the space occupied by the removed bone being filled by a firm and even callus."

Sir A. Cooper mentions a case in which, after the sawing off of the protruding end of the tibial fragment, no union occurred, and the boy was left permanently lame.

Fractures of the bones of the foot are not met with in children, except as the result of crushing force, and they are, so far as my observation has gone, always compound. Discussion of them here would be only in regard to the question of amputation, and this must be settled in each case on well-known principles.

DISLOCATIONS.

Dislocations or luxations are proportionally much less frequent in children than are fractures. Thus, Malgaigne, among a total of six hundred and forty-three cases, found only twenty-one, or a little less than one-thirtieth, between the first and the fifteenth year of life; while out of thirteen hundred and seventy-seven fractures, one hundred and fourteen, or about one-twelfth, belonged in that period. And in the records of ten years (1878–1887 inclusive) at the Children's Hospital in this city, there are but thirty-four cases of luxation as against five hundred and four of fracture. It is not difficult to account for this rarity of dislocations, when the small leverage afforded by the bones of children, the comparative strength of the fibrous tissues about their joints, and the slight amount of their muscular resistance are taken into consideration.

[3] Cases and Practical Remarks in Surgery, 1767, p. 285.

[4] Contributions to Practical Surgery, p. 42.

Mr. Jonathan Hutchinson[1] has advanced the curious view that the lesions supposed to be luxations in children are in reality epiphysial separations. Thus, he says that he has never met with a simple luxation of the shoulder in a child, but has seen many cases of detachment of the upper epiphysis of the humerus. Luxation of the elbow, he says, is not uncommon in adults, but in children is exceedingly so, the lesion supposed to be of this nature being separation of the epiphyses. With all respect for its distinguished author, I feel warranted from my own experience alone, to say nothing of that of the profession at large, in declaring that this proposition is wholly untenable. I am not aware, indeed, that it has ever been accepted by any one.

Dislocations may be pathological, the result of disease or of abnormal laxity of the joints, or traumatic, produced by violence. To the former class belong the congenital dislocations, met with especially in the hip, and those which occur in the course of fevers. Traumatic or accidental luxations may be due to direct violence, applied at once to the end of the bone which is displaced, knocking it out of its connection, or to indirect, applied at a distance, and acting on the bone as a lever. One point should be noted in the causation of such injuries in children: they are often produced by pulling upon the limbs, by which the ligamentous structures about the joints are put upon the stretch, and then the bones fail to go back into their proper relative position. This does not occur in the more rigid joints of adults.

Dislocations may be *complete* or *partial*. A *compound* dislocation is one in which the displaced end of the bone is exposed to the air by lesion of the soft parts; all others are termed *simple*. When a luxation is accompanied by other serious injury in its neighborhood, such as fracture, or great damage to vessels or nerves, it is said to be *complicated*. When the bone displaced remains in the abnormal position first assumed by it, the luxation is said to be *primitive;* if it passes into another, this is said to be *consecutive*. The term *old* is applied to a luxation which for any reason has existed without correction for so long a time that changes are likely to have taken place which render reduction difficult.

The mechanism by which bones are dislocated is not always easy to determine in adults; and in children the difficulty is much greater, since they can very rarely give a clear idea of the way in which an accident has befallen them.

---

[1] Medical Press and Circular, March 19, 1884.

The symptoms of luxation are pain, limitation of motion (passive as well as active), and deformity of the affected joint. Sometimes the absence of the dislocated bone from its proper position, and its presence elsewhere, can be clearly made out by feeling, if not by sight. Swelling is apt to occur very speedily, and may obscure the condition of the part. Ecchymosis very commonly ensues, just as in cases of fracture. There is also often a sound produced by the contact of the bones, which is to an inexperienced ear not unlike the crepitus of broken ends.

The diagnosis of a luxation is of great importance, since upon its early reduction may depend the usefulness of the limb in after-life. Usually the question is between fracture of the bone close to the joint, and displacement. Often the fact of the limitation of mobility will be sufficient to show that the latter lesion is present; if anæsthesia has been induced, as it always should be in cases of doubt, this sign is of more value.

If during the examination the deformity is corrected, and the normal mobility of the part restored, the diagnosis of luxation may be regarded as established. Let it be remembered that in children we are not so likely as in adults to have the moment of reduction indicated by a loud snap.

It must be borne in mind, and especially as regards the elbow, that luxation and fracture may be combined. Hence every case of dislocation should be carefully watched, after reduction has been effected, until the freedom and power of motion show clearly that the joint has resumed its normal state.

The prognosis of luxations in children is, as a general rule, much more favorable than in adults. The degree of violence to the soft parts is usually less, and the reparative powers of the tissues are of course greater. Yet the surgeon must not be too ready to promise a perfect result; since there may be stiffening of the affected joint, weakness of the limb, numbness or pain in the nerves which have been pressed upon, for some time, and the possibility of such after-consequences should be made known beforehand to the little patient's friends.

INTRA-UTERINE LUXATIONS are of rare occurrence, and, when met with, have almost always been the result of disease. Of all the joints, the hip is most frequently so affected, and on both sides. Cases are on record in which both knees have been dislocated, or rather abnormally movable, forward. In one case, reported by Rodrigue,[1] there was a dislocation of the left humerus, together with united fracture of the corresponding forearm; both lesions being accounted for by a blow received by the mother on her abdomen in the fourth month of her pregnancy.

LUXATIONS DURING BIRTH.—These must be of extremely rare occurrence. Scanzoni[2] says that he never met with luxations in the newly-born, "yet they occur, sometimes as congenital lesions, sometimes, and not very seldom, in the hip, as the result of powerful traction made on the lower extremities."

SPECIAL DISLOCATIONS.

LUXATIONS OF THE VERTEBRÆ.—A number of cases are on record in which, usually by great violence, separations of the vertebræ have taken place, and the relations between two of them have become changed.

Boyer[1] quotes from J. L. Petit an account of a child six or seven years of age "lifted up by a man (in order to see London, according to the vulgar saying) who took hold of the forehead and back of the head. The child struggled, became agitated, and died. It is to be regretted that there was no anatomical examination, though there is little doubt that the first vertebra was luxated upon the second."

Horner[2] saw a boy aged ten, who by a fall of twenty feet had sustained a luxation of the left oblique process of the fourth cervical vertebra forward, as shown by the distortion of the neck and by the position of the fourth spinous process. No attempt at reduction was made, on account of the risk involved. That this fear was not idle is shown by the case quoted by Boyer[3] from Petit-Radel, in which a child similarly injured died under the hands of the operator.

When only one oblique process is thus displaced, the injury is less grave than when it affects both sides. Occasionally one oblique process is driven forward, the other going backward; a rotary movement being given to the head and upper part of the neck. In any of these cases the chief danger is from interference with the spinal cord or with the nerves given off from it. Hemorrhage into the spinal canal, from ruptured vessels, or actual pressure by the displaced bone, may paralyze respiration.

If treatment is instituted, it should be with a view to disengaging the luxated process or processes, by extension of the neck and rotation in the direction opposite to that of the displacement. In the case of a boy aged twelve, W. J. Morton[4] succeeded in reducing a luxation of the fifth oblique process, by suspension from the head, with rotation. Stimson[5] quotes from Blasius a case of Richter's in which a boy aged eleven or twelve reduced a dislocation in his own neck; also one in which an accidental reduction took place from the patient falling out of bed.

Luxation of the dorsal vertebræ has been met with. Stimson[6] says, "In one case that has been under my observation for two years, the patient, a girl fourteen years old, has been in good health, although she remains completely paralyzed below the level of the breasts; the injury appears to have been a diastasis at the fourth or fifth dorsal vertebra, and was caused by a fall down the narrow air-shaft of a tenement-house from a height of about sixty feet." A case of luxation of the twelfth dorsal vertebra from the first lumbar, by crushing force, in a boy of eleven, was reported by Swan,[1] who saw the patient eight years afterwards. In these cases there is no certainty that there has not been fracture, as well as luxation, unless the condition is determined by an autopsy. Sir Charles Bell [2] records that "an infant" was run over by a diligence; it died of croup thirteen months afterwards, and a post-mortem showed the twelfth dorsal vertebra completely luxated; the direction of the displacement is not stated, but it is said that "a very small portion of the bone had been broken off."

[6] Op. cit., p. 158.

Two symptoms will be present in all these cases,—distortion of the vertebral column, as shown by the altered relation of the spinous processes; and paralysis, more or less complete, of all the parts below the seat of injury.

LUXATIONS OF THE LOWER JAW.—These are very rare indeed in children. Sir A. Cooper has recorded one produced in a boy by the effort to stuff an apple into his mouth. Malgaigne quotes from Delamotte the case of a girl eleven or twelve years of age who was kicked by a horse, the jaw being dislocated and fractured at the same time. Mr. E. Morris[3] has reported a curious case in which a girl of fifteen had her jaw displaced during sleep, from the act of sucking her thumb. Another occurred to Ballard.[4]

Malgaigne quotes from Tartra a case in which one condyle only was displaced during convulsions, in a child fifteen months old; the child was six years old when treated.

The symptoms in double dislocations are very characteristic. The mouth is more or less widely open, and fixed so; there is apt to be severe pain from tension of the muscles as well as from pressure on nerves. In the unilateral form the jaw is twisted to the opposite side from that on which the displacement has occurred.

The treatment consists in depressing the angle or angles of the jaw, and elevating the chin. In Tartra's case the jaw was fixed; it was forcibly depressed, and by means of small wedges a considerable improvement was effected, but the ultimate result is not known.

LUXATIONS OF THE CLAVICLE.—Either end of the clavicle may be dislocated.

Luxations of the Sternal End.—The clavicle may be displaced from the sternum forward, upward, or backward; but I know of only two recorded cases of any form except the first-named in a patient under fifteen years of age.

[2] Injuries of the Spine, London, 1824.

[3] British Medical Journal, August 31, 1872.

[4] Mason, Lancet, February 23, 1878.

Fergusson[1] says, "I once saw a case of displacement of the inner extremity of this bone in a newly-born infant, which had happened during birth. The end rested in front of the sternum, and could be pushed into its proper place with great ease; but when left alone, it immediately slipped out again. Nothing was done, a new joint formed, and the child afterwards possessed as much power in the one arm as in the other."

Gross[2] records an instance of "congenital" luxation forward and upward, seen by him when the child was three months old. Wright[3] has reported a case of dislocation of the sternal end of the clavicle downward and forward, in a child aged ten months, by a fall out of bed. Melier is quoted by Malgaigne as having seen this accident in a girl aged four years, whose arm had been forcibly pulled upon. Mulvany[4] reports the case of a boy aged fifteen, thrown heavily upon his back at sea, in whom several of the left costal cartilages were dislocated behind the sternum, and the right clavicle was dislocated forward. It would seem likely that here the clavicle was fixed, and the sternum wrenched away from it. Hamilton mentions having seen two cases in boys, in neither of which could permanent reduction be effected.

In these cases there must be rupture of the sterno-clavicular ligaments (of the anterior one at least), and perhaps of the interclavicular and costo-clavicular ligaments. The displaced interarticular cartilage may sometimes be the cause of the difficulty experienced in maintaining reduction.

The diagnosis lies between this luxation and fracture of the clavicle close to the sternal end, or epiphysial separation. But the smoothly-rounded end of the bone, and the absence of the prominence at one side of the interclavicular notch, should indicate the true character of the lesion.

The treatment must consist in drawing the shoulder forward, so as to tilt the displaced end of the bone backward, and in making pressure upon the latter with a pad held in place by adhesive strips. Anæsthesia should be employed if there is any difficulty in the reduction.

A remarkable case is recorded by Morse[5] in which a girl aged eight was knocked down and run over, sustaining a dislocation outward (forward?) of the right clavicle, and a dislocation backward of the left, the first rib being also fractured. She had great venous congestion of the neck and head, which was relieved by the reduction, after much difficulty, of the left clavicle. Subsequently she did well. Hulke[6] gives another instance of backward luxation of the right clavicle, in a girl aged ten; the child was knocked down and run over, and it was supposed the horse stepped on her. There was great dyspnœa, relieved by drawing the shoulders backward. She made a perfect recovery.

Luxations of the Acromial End.—The clavicle may be displaced from the acromion either upward or downward.

Hamilton reports one case of the former kind, seen by him in a girl four weeks old; it was congenital, and reduction could not be maintained.

A curious case of luxation downward is quoted from Melle by Malgaigne. It was that of a soldier, who at six years of age had his shoulder borne down by a great weight. The corresponding humerus was luxated at the same time, and remained so.

Chase[1] saw a case in which a boy aged eight fell, striking on his shoulder, and forcing the clavicle below the acromion. Under ether, reduction was easily effected by drawing the shoulder upward and backward.

The diagnosis of acromio-clavicular luxations can hardly present great difficulty, but the treatment may. Reduction is easily accomplished; but the displacement is extremely apt to recur. Support of the arm and hand by means of a well-arranged sling may be employed, and ultimately the complete restoration of function is probable.

Luxations of Both Ends.—Two cases are upon record in which luxation of both ends of a clavicle occurred simultaneously.

One, reported by North,[2] was that of a boy aged fourteen, who fell backward; the whole bone seemed rotated downward and forward on its long axis, its middle portion looking as if fallen in. Reduction was easily effected by pressure, and maintained by means of a "yoke" splint.

The other case, recorded by Haynes,[3] was that of a weakly girl aged thirteen, who was reaching up behind her head, when the clavicle gave way, the sternal end being luxated forward, and the acromial end upward. Reduction could be readily made, but the deformity reappeared.

LUXATION OF THE STERNUM (the manubrium upon the body of the bone) is recorded by Ancelet[4] as having been seen by him in a boy aged thirteen, who met with the accident while exercising upon a trapeze. There was intense pain at the seat of injury, aggravated by any respiratory effort; and the upper edge of the body of the bone was distinctly felt as a transverse ridge. Reduction was effected by strongly bending the body backward.

One case of congenital luxation of the xiphoid or ensiform cartilage is quoted by Malgaigne from Seger; an abnormal degree of mobility seems to have been the chief symptom, and a spontaneous cure ensued.

LUXATIONS OF THE RIBS have been observed in a few instances in early life. By great direct violence two of the lower ribs were driven forward from their attachments to the vertebræ, in a boy aged eleven, seen by

[3] British Medical Journal, January 27, 1872.

[4] Gazette des Hôpitaux, June 4, 1863.

Dunne, and in a girl aged fifteen, seen by Finucane.[1] Another case, affecting the first rib, has recently been reported by Quint.[2]

Anteriorly, the ribs may be displaced from the sternum. Flagg[3] reported the case of a girl aged ten, who ran against a table, striking the front of her chest; forty-eight hours afterwards she was exercising violently, when she felt pain, and "something gave way;" the fourth rib was found to be dislocated forward on the sternum. The result is not mentioned.

With regard to the diagnosis, prognosis, and treatment of such injuries, it is impossible to make any general statements, in view of the very limited experience recorded.

LUXATIONS OF THE HUMERUS are comparatively rare in early life; Malgaigne had collected but four instances under fifteen years of age. Yet Rodrigue[4] saw one which had occurred before birth. Stimson says that Bardenheuer quotes from Knox two cases in which the humerus was dislocated by obstetric manipulations. Mitchell[5] has reported a case in which a child, delivered by version by the foot, was found to have the head of one humerus luxated into the axilla; reduction was effected, and electricity was successfully applied for the relief of the paralysis of the muscles of the arm which ensued.

R. W. Smith[6] has described in detail five cases in which this lesion was congenital. In one congenital case, reported by Bouvier,[7] the patient having attained the age of sixteen years, Gaillard succeeded after several attempts in effecting reduction. In two of Smith's cases, and in one reported by Küster,[8] both shoulders were concerned.

Clippingdale[9] showed to the West London Medico-Chirurgical Society a child seven months of age with the head of one humerus in the axilla; the bones of the arm were all rudimentary, and the hand had only four digits. The explanation given was that the dislocation was intra-uterine, "due to sudden and irregular contractions of the uterus, the result of fright."

Flower[10] mentions an instance of dislocation forward, in a child only fourteen days old; the arm, it is said, had been violently pulled and twisted.

I myself saw, in 1864, the same shoulder twice dislocated forward within four months, in a little girl two years old; on both occasions the accident occurred as the child was lifted out of its cradle. Ashhurst has reported[1] a subcoracoid luxation in a girl two and a half years old, who had been swung round by the arm.

[10] Holmes's System of Surgery, 3d ed., vol. i. p. 972.

A case of spontaneous luxation of the humerus is mentioned by Keen[2] as occurring in a badly-nourished child aged two; it was easily reduced, and did not recur; but the bone subsequently became necrotic. Another, in a girl aged twelve, after a fever, is recorded by Sir A. Cooper.

Hamilton treated a girl of fourteen who had her humerus dislocated into the axilla by a fall on the sidewalk. Stimson[3] merely mentions as the cause of a subspinous dislocation "the throwing of a stone, by a boy ten years old." Another instance of this (in children) rare displacement has been reported by Chambers,[4] in a boy aged four years. The mechanism of its production was not known, but the position of the head of the bone was clearly made out, and the arm was shortened by an inch. Reduction was effected by extension and manipulation.

A case of compound luxation has been reported by Scott;[5] it occurred to a boy aged fourteen, who was thrown from a horse and dragged. The head of the humerus lay exposed on the front of the pectoralis major muscle. Reduction was effected, and the boy recovered with a useful arm.

So far as can be judged from the small number of recorded cases, it would seem that the luxation of the humerus forward is in children the most frequent form; but the great laxity of the capsule in them must be borne in mind; and my own belief is that the head of the humerus escapes first into the axilla, and then is drawn up under or in front of the coracoid process. In three cases only—Stimson's, Chambers's, and one of R. W. Smith's,—was the head noted as displaced backward.

The congenital luxations of the shoulder would appear to have been noticed as "something wrong" by the parents, and recognized by the surgeon from deformity and limitation of motion. In traumatic cases there is pain, with more or less complete loss of use of the arm, and deformity.

Dugas's test may be of much use in these cases; it consists in placing the elbow at the side, and trying to carry the hand over to the sound shoulder, which cannot be done if the head of the humerus is displaced. I am not sure, however, that in children the laxity of the ligaments may not sometimes be such as to lessen the value of this sign in them.

Reduction is usually effected without difficulty, by manipulation alone, in young children. Anæsthesia is not needed. After the age of eight or ten years there may be more resistance encountered, and it may be necessary to give ether and to make extension with the knee or the heel in the axilla.

The after-treatment consists in keeping the limb at perfect rest, which is best accomplished by binding it to the side for a few days, after which the hand and forearm may be simply supported in a sling.

[3] Op. cit., p. 241.

[4] College and Clinical Record, September, 1889.

[5] Lancet, March 4, 1834.

Luxations of the Elbow, like fractures of the lower part of the humerus, are very common in children. One reason of this is the great slackness of the ligaments in them; probably every one has noticed the great degree of extension and flexion of this joint which they possess, as compared with that possible to adults. Then, again, the joint is a complex one, and the bones entering into its formation are in early life smooth and rounded, acquiring their strong features only with their full development.

Either one or both bones of the forearm may be dislocated upon the humerus; in the former case the relation between the radius and ulna must, of course, be also changed. Each of the various displacements which are included under these general terms has its special mechanism. I believe, however, that in nearly all cases not only is there a stretching of the ligaments, but a twist is also impressed upon the part, so that the articular surfaces slide, as it were, around one another.

Luxation of both bones backward is by far the most frequent of these injuries. In Krönlein's tables, quoted by Stimson,[1] out of ninety-four cases of this kind, twenty-two were in children between one and ten years of age, and forty-four between eleven and twenty. Hamilton states that out of seventy-two cases collected by him twenty-nine were under fourteen years of age; and speaks here, but nowhere else, of one of them who was only four. I have myself never seen such an injury in a child less than six years old, nor do I know of any report of one except this mere mention.

It has occurred to me to see two cases of this kind in one family: a boy aged six, in 1878, and his brother aged ten, in 1887; in each instance the cause was a fall on the hand, and reduction was easily effected.

For the most part, the symptoms of luxation backward are distinctive: the forearm is helpless, slightly flexed, usually more or less decidedly pronated; the antero-posterior diameter of the elbow is greater than normal; the olecranon is felt and seen projecting behind the condyles of the humerus, and the finger can be pressed into a gap above it; the rounded end of the radius is below the external condyle; passive motion, flexion especially, is limited, and the distance from the bend of the elbow to the wrist is shortened. Under such circumstances, it would seem as if mistake were impossible; but swelling comes on very rapidly, and may so mask the parts as to prevent the detection of the injury. Moreover, there may be, along with the luxation, fracture of one or both condyles of the humerus, or of the coronoid process of the ulna. In 1877 I saw a boy about fourteen years old, with a backward luxation of the elbow, the radius and ulna being widely separated. No fracture could be detected; reduction was easy by extension. The account he gave was not clear, and I am at a loss to account for the condition.

Now, it is of great importance to determine not only the fact of the displacement of the bones, but also the question whether or not there is fracture; and hence in any case of doubt the child should be etherized, and a most careful investigation made. Occasionally reduction is at once and easily effected, with complete restoration of the normal form of the joint, as well as of its mobility. But the child may be frightened and resist; there may be so much swelling as to obscure the parts; above all, there may be a suspicion of fracture as well as luxation, in which case the prognosis and the treatment would be materially influenced. Cases are upon record in which, even in expert hands, the supposed reduction had not really been accomplished. The rule should, therefore, be absolute, that in any case of either doubt or difficulty anæsthesia is to be induced. Sometimes, even with every advantage, it is impossible to determine the exact seat of fracture; and in any such case a prudent surgeon will be very guarded in his prognosis.

---

[1] Op. cit., p. 21.

As to the method of making the reduction, we should be guided by mechanical principles. The coronoid process must be disengaged from behind the lower end of the humerus; and in order to do this the forearm should be still further extended on the arm, with slight traction on the hand.[1] I have never seen a case in a child in which this manœuvre was not sufficient, the bones instantly slipping into place, unless there was also fracture.

Spencer[2] has reported the case of a boy aged ten, with luxation backward of both bones of the forearm, in which three attempts at reduction failed; an incision was made, and the olecranon removed, when a tight band was found across the back of the humerus; this was slackened and slipped over the end of the bone, after which the reduction was effected, and a good result was ultimately obtained.

Of course, when the dislocation is of long standing, it is a different matter. Hamilton mentions a boy of twelve whose elbow had been out six weeks and could not be reduced. In another case, that of a boy aged seven, the luxation dating back nine weeks, the arm being nearly straight, flexion was made, and the olecranon gave way. In still another old case, the triceps was divided and reduction then made by flexion. Although in these last two cases the bones were restored to position, the ultimate results were not altogether satisfactory as regards motion. Beck[3] has reported a curious case in which a boy aged seven had a backward luxation of the left elbow, which had existed seven months; while at play he had a fall, by which the adhesions were broken up, and reduction was then effected without difficulty.

---

[1] Some surgeons, and notably Sir A. Cooper, have advised a different method, thinking it better to flex the elbow, and to draw the hand forward with the limb in this position. The advantages of the plan mentioned in the text are so much greater, both in theory and in practice, that I think it should always be employed, and therefore have allowed it to stand alone.

[2] Lancet, November 16, 1889.

[3] New York Journal of Medicine, May, 1857.

Maisonneuve,[1] in the case of a boy aged fifteen, with a backward luxation of the elbow of forty-seven days' standing, succeeded in effecting reduction by upward traction upon the humerus from just below the insertion of the deltoid, and downward upon a "lac" applied directly over the olecranon, and forming a figure-of-eight around the forearm.

My own experience in old luxations of the elbow in children has been limited to cases which were beyond remedy; and I have never seen one in which there was not a probability at least that the injury had been complicated with fracture. Sometimes, in old unreduced luxations of the elbow, the condition is such as to justify a resort to complete or partial excision of the joint; the latter operation is reported by Davies-Colley[2] to have been practised by him in the case of a boy aged eleven, with good result.

Even when reduction has been readily and fully effected, there is not always a certainty of success. Hamilton mentions a case in which a boy aged eight, with such a history, had still a stiff joint, at a right angle, more than four years afterwards.

Malgaigne laid stress upon the possibility of *incomplete* backward luxation of the elbow, but it does not seem to call for special discussion here. He says that in old cases reduction is easier than in the complete form, mentioning a boy aged ten in whom he succeeded after the lapse of nearly four months.

I myself recently met with a case in a boy aged fourteen, who had been thrown down in playing the day before. Flexion and extension were both somewhat limited, the former especially; pronation and supination seemed normally free. On measurement, the distance from the acromion to the tip of the elbow was greater by one-fourth of an inch than in the sound limb, and the circumference of the elbow was increased half an inch. Reduction was easily effected under ether given to the first insensibility, and the motions of the joint were completely restored.

The symptoms and treatment do not vary materially from those of the complete form already described.

Other dislocations of the bones of the forearm upon the humerus have been met with,—outward, inward, and forward. As to the two former, I would suggest that they are brought about, in part at least, by the formation of the articulating surface of the humerus, by reason of which the ulna, carrying with it the radius, slides around one or other of the ridges limiting the trochlea. The lateral ligaments of the joint are put upon the stretch, when the ulna is drawn away from the humerus, and, as it goes back, the ridge in the middle of the sigmoid cavity fails to fit into the depression in the trochlea, but is applied to one or the other side of it. In other words, I think that, when both bones of the forearm suffer displacement together, the ligaments are stretched, and the ulna comes away from the trochlea; as it goes back, the natural relation fails to be restored, generally because the coronoid process slips behind the humerus, but sometimes because the ulna goes to the inner side or to the outer side of the trochlea. Hamilton mentions the case of a boy aged eight in whom the radius and ulna were displaced outward and upward (backward); firm pressure being made upon the radius from the outside, "the bones assumed suddenly the position of a backward and upward dislocation, from which position they were readily reduced to their original sockets by simple extension."

[2] British Medical Journal, February 2, 1889.

Complete luxation here is when the articular surfaces of the radius and ulna are both wholly separated from that of the humerus. I know of scarcely any instances of this kind in children, except in the backward direction. Chapel's case (forward), and some of the divergent dislocations, as, for example, when the radius slips out forward and the ulna goes backward, are complete; but for the most part there is some contact between the articular surfaces. I have never seen an instance in which there was a complete separation of both bones from the humerus, either outward or inward, in a child, but have several times treated backward luxations in which the bones had suffered outward displacement also.

Varick[1] has reported the case of a boy aged nine who fell from a wagon on his back, with his elbow flexed, and sustained a complete outward luxation. Reduction was effected by moderate extension, with lateral pressure, ether having been given; and perfect recovery ensued. Prewitt,[2] in the case of a girl aged five, who by a fall from a swing five weeks before had luxated the elbow inward, found reduction impossible.

A very remarkable case is quoted by Malgaigne from Chapel: a boy aged fifteen struck his arm roughly against a wall, and forced the whole forearm outward and forward, so that the epicondyle was behind the ulna. Reduction was effected at the second attempt, by extension and pressing the bones into place.

Sir A. Cooper[3] mentions the case of a boy aged eight who by a fall on the hand sustained a luxation of both bones inward. The injury was supposed to be a fracture, and was treated accordingly. A month later, on the removal of the splints, the sigmoid cavity of the ulna was found applied to the epitrochlea; flexion was limited to ninety degrees, extension to one hundred and forty-five degrees; there was very little voluntary motion, but pronation and supination could be made passively.

Dr. A. F. Stifel, of Wheeling, West Virginia, has reported to the American Medical Association a case of incomplete luxation inward of the elbow, in a girl aged three and a half years; the swelling was so great as to prevent a correct diagnosis for several days; reduction was repeatedly attempted, but without success. Dr. S. discusses at length the pathology and symptoms of this injury, which he thinks occurs more frequently than is generally supposed, its true nature often escaping recognition. He advises traction and lateral pressure for reduction.

[2] St. Louis Courier of Medicine, January, 1879.

[3] Op. cit., p. 465.

It is impossible to imagine such displacements occurring without considerable laceration of the ligaments about the joint, and one would suppose other structures would suffer also.

A case of compound luxation, with rupture of the artery and stretching of the median nerve, in a boy aged fourteen, is reported by Ferret;[1] the nerve perished, and there was gangrene of some of the fingers, but a good result ultimately ensued. Malgaigne[2] quotes from Michaux an instance in which, in the attempt at reduction of a luxation outward and backward in a boy aged ten, the artery and nerve were both torn, and gangrene made amputation necessary.

Clutton[3] has recorded a case of complete compound dislocation of the elbow outward and backward, in a boy nearly thirteen years old. The bones having been reduced, drainage was made, and the anterior wound left open. The result was a complete restoration of movement.

As to the symptoms, the elbow is, of course, wider than natural, and the deformity of outline will indicate the character of the lesion.

Fergusson[4] says, "It is impossible to say what dislocations may not take place in this articulation. I have myself frequently seen the joint in such a disordered condition, from injuries of old date (probably luxations and fractures combined), that the most experienced anatomists have been unable to appreciate the true condition of the ends of the bones." This is especially true in the case of children. I believe that the most usual of these irregular displacements is that in which, the head of the radius slipping out from the grasp of the annular ligament, this bone starts up in front of the condyle, while the ulna goes backward. And it will readily be seen that by a slight further twist the head of the radius may pass to the outer side of the condyle. A case of this kind, in a boy of eleven years, came under my care at the Pennsylvania Hospital in 1886; reduction was easily effected. I think this is the true explanation of the two cases, in boys aged respectively thirteen and fifteen, related by Sir A. Cooper; and perhaps it is applicable in the other instances, in adults as well as in young subjects, which are upon record.

Luxation of the radius alone has been many times observed. Generally the bone goes *forward*. This lesion may be congenital, as in a case reported by Heelis,[5] where the bone of the left side was completely, and that of the right partially, displaced; the former was reducible on flexion, the latter irreducible; the humeral condyles were very small, and there were evidences of defective development of the nervous system. Krackowizer[1] recorded a case in which such a luxation was ascribed to the operation of turning in delivery. Danyau[2] mentions the case of a girl aged three whose hand had been pulled upon in supination; the radius was displaced forward, and could not be reduced. He quotes Loir as having met with the lesion on both sides in the dead subject; the heads of the bones were much lessened in volume.

[4] Practical Surgery, 5th ed., p. 215.

[5] Lancet, August 7, 1886.

This luxation has been perhaps oftenest caused by careless traction on the forearm, in very young children. Collier[3] was, I believe, the first to report a case so produced, in a child two years and a half old, whose mother lifted it by its wrists. The lesion was thoroughly well described by Goyrand,[4] who assigned this cause for it. Sir A. Cooper thinks it is produced by falls on the hand, and cites an instance in point, in a boy seven years old.[5] Hamilton saw it in a girl aged four, who had fallen from a swing and held on by her hands. The subluxation, or incomplete form, in which the head of the radius does not wholly leave the condyle, has been recently described and discussed as a new thing by several writers.[6] Perhaps this is the lesion usually caused in children under five years of age by traction on the hand; but the complete displacement may also occur in them, as well as in older children. The symptoms of either are pain in the elbow; the forearm flexed to a right angle with the arm, and more or less completely pronated; passive motion limited, and the attempt at it painful; and the head of the radius felt in its abnormal situation.

Reduction, according to some, is very easily effected by supinating the hand, and pushing the head of the radius into its proper position. But we have the testimony of Hamilton, Sir A. Cooper, and Malgaigne, that the replacement is not always possible. Danyau's case, before quoted, was of this character; and many other such instances are on record. Sometimes there is a marked tendency to recurrence of the displacement.

It may be mentioned here that this luxation is apt to be accompanied with dislodgement of the ulna backward; and sometimes, as in three cases recorded by Hamilton, the latter bone is broken instead, as if the force exerted would have caused luxation but for the giving way of the bone. Such a view is more plausible in Hamilton's cases, where the fracture was in the upper third, than in one observed by Stimson,[7] where the fracture was at the middle of the ulna. Such associated injury does not appear to constitute any complication in treatment of the dislocation, which is to be reduced as soon as possible; the limb is then to be kept at rest, with the elbow flexed at a right angle, and the splints elsewhere described applied to remedy the fracture.

[7] Treatise on Dislocations, pp. 340–41.

Sir A. Cooper mentions a case in which a boy aged twelve had the radius luxated upward and outward (forward?), with fracture of the olecranon, by a severe blow. Thirteen years afterwards he had only imperfect extension and flexion of the joint; and in the latter motion the head of the radius would slip out of place.

Luxation of the head of the radius backward has been observed as a simple uncomplicated lesion. Hamilton mentions a case seen by him in which it was said to have been the result of convulsions when the boy was but one year old. Danyau[1] saw it in a boy aged eleven; it had occurred five weeks before; the elbow was semi-flexed, and the power of voluntary pronation and supination was lost; reduction was effected with difficulty.

Phillips[2] has recorded the case of a girl aged seventeen who had congenital luxation backward in both elbows, the heads of the radii lying behind the condyles; extension and flexion were free when the hands were semi-pronated. In another instance, reported by Pye-Smith,[3] there was such a congenital luxation on the left side only; the woman was one of eleven children, eight of whom had abnormal joints, imperfectly developed hands and feet, and malformed nails. As a result of such displacements, or of those due to accident in childhood, the joint undergoes changes of shape, which have been studied and described by Allan.[4]

This lesion has been repeatedly observed along with fracture of the inner portion of the lower end of the humerus. It seems to me that the mechanism which at once suggests itself for such an injury is the true one; that there is at the same time a twist of the hand into supination, and an abducting force, so that the trochlea and the portion of bone just above it are wrenched away by reason of the engagement of the former in the sigmoid cavity of the ulna. Should the position of the limb, the direction of the force, or the slackness of the ligaments be such as to allow the ulna to slip away from the trochlea, there would be merely a luxation backward of both bones.

Luxation of the radius outward has been observed in a few cases in children; it is perhaps for the most part secondary to luxation forward, although in one case quoted by Stimson[5] from Von Pitha it would seem to have been produced directly, a grown person treading on the elbow of a girl nine years old, who lay asleep on the floor with the arm extended in supination. The head of the bone can be recognized at the outer side of the humeral condyle, and reduction effected by simply pushing it back into place. Sometimes this has been found impossible, the annular ligament crumpling up, and failing to receive the head of the bone; and the dislocation has in some instances recurred very obstinately.

[2] British Medical Journal, April 21, 1883.

[3] Lancet, December 8, 1883.

[4] Glasgow Medical Journal, July, 1880.

[5] Op. cit., p. 329.

Luxation of the ulna alone, backward, has been observed in one case by Von Pitha,[1] a little girl aged six having the extended arm forcibly flexed at the elbow. This joint was twisted toward the ulnar side, and the prominence of the olecranon behind and the trochlea in front could be easily made out; the radial head was in place; flexion gave great pain. Reduction was effected by slightly increasing the extension until the coronoid process slipped over the trochlea.

Before leaving this subject I feel constrained to mention again the difficulties which beset the surgeon in dealing with injuries about the elbow. The various luxations which have now been discussed are not easy to recognize in practice, even in thin subjects, and when uncomplicated. Even in dissected specimens it may be hard to determine the exact character of the lesions. Upon the occurrence of injury, swelling usually comes on with great rapidity, and masks everything. Fracture may be present, and the crepitus and mobility due to it may mislead the surgeon. Hence the utmost care should be taken in examining every case, anæsthesia being almost always requisite; a guarded diagnosis and prognosis only will be given by a prudent surgeon; and it behooves us to be charitable to the utmost in judging of the results of the practice of others.

LUXATIONS OF THE WRIST, formerly described by surgical writers as of common occurrence, are now known to be extremely rare; the cases supposed to have been of this character having probably been fractures close to the joint. A number of the instances which have been placed on record are open to much doubt, as, for example, that of Haydon, published by Sir A. Cooper,[2] in which a boy aged thirteen, thrown from a horse, is said to have had one wrist luxated backward and the other forward. Here there was probably a double fracture. I shall mention only a few cases which seem to be unquestionable.

In one instance[3] a boy aged nine fell from a tree a distance of over thirty feet; the left wrist was dislocated backward, and was easily reduced by extension and pressure, "the patient immediately regaining the use of the joint." Roland[4] saw a boy about twelve years of age who by a fall had the carpus displaced forward (on the palmar surface of the radius and ulna); the hand was fixed at nearly a right angle with the forearm, and the fingers were strongly flexed. During the administration of ether the bones slipped into place. Aitken[5] reports the case of a boy of sixteen who sustained a like injury by falling from a tree; by traction on the hand, reduction was effected with a snap, and, although the wrist remained swollen for three months, a perfect recovery ensued. Walker[1] saw a dislocation backward in a boy aged sixteen, who was pushing a cask, when it slipped back, and his elbow came against another cask; reduction was easily effected. In 1874 a boy about twelve years old was brought to my office who had a few minutes before fallen about eight feet and "twisted his hand all out of place." His comrades immediately pulled upon it, and it was reduced, when he came to me. There was certainly no fracture, and the use of the hand was restored completely. Hardyman[2] reports the case of a boy aged twelve who fell from a height of about two feet forward on his hand, sustaining a luxation backward of the wrist; this was easily reduced, and a green-stick fracture of the radius was then discovered. Sherburn[3] has reported the case of a boy aged fourteen who fell twenty feet, and sustained a luxation backward of the wrist; the hand was somewhat abducted and the fingers were flexed. Reduction was effected by traction in extension, with gradual flexion and pressure. Some stiffness followed.

[3] Hospital Report, Lancet, June 12, 1841.

[4] Philadelphia Medical Times, June 7, 1879.

[5] Lancet, June 11, 1887.

In a true dislocation backward of the wrist, the deformity closely resembles that of fracture in that neighborhood. But, unless swelling has taken place to a very marked degree, the rounded shape of the carpal bones can be traced at the back, while in front the radius and ulna can be distinctly felt, with the concavity formed by them at their lower end. On strong extension the deformity disappears, and the joint can at once be moved as usual. Careful examination should always be made for the crepitus which would attend fracture.

Dislocation forward presents the opposite condition; the radius and ulna can be traced to their lower termination, while the carpus projects at the palmar surface; but the flexor tendons and the strong annular ligament are rendered extremely tense, and may hold the hand in flexion (see Roland's case, above).

One indication is perfectly clear in all these cases,—viz., that strong extension is to be made upon the hand. If this completely corrects the deformity, the movements of the joint should be tested, and then, if there is no crepitus, the parts should be placed at rest on a properly-padded splint. Swelling and tenderness may persist for a few days, and in that case should be treated by wet dressings. Leeches may be applied if there is decided inflammation.

Lateral luxations of the wrist are described by writers, but are probably always pathological, the result of previous disease of the joint, and need not be dwelt upon here.

Luxations of the lower radio-ulnar articulation have been described, but there is very little known about them. There may be a diastasis of the one bone from the other, the triangular cartilage going with the radius. It seems to me that these injuries would be more correctly designated as partial luxations of the wrist, the hand being forced into extreme pronation or supination and at the same time adducted or abducted. I do not know that such a case has ever occurred to me.

[1] Lancet, September 10, 1887.

[2] Ibid., November 5, 1887.

[3] Ibid., May 18, 1889.

Sneddon, in the article before quoted,[1] expresses the opinion that the injury supposed to be subluxation forward of the head of the radius may be in fact a displacement at the wrist; but I must confess my inability to understand his view.

Compound luxations of the wrist are very serious injuries, and may require resection or even amputation; although it should be remembered that in children the reparative powers are much greater than in adults. No general rules can be laid down for the treatment of such cases, which call for the utmost skill and judgment on the part of the surgeon.

LUXATION OF THE METACARPUS from the carpus has been seen by Stimson in a boy aged fifteen, who had fallen forty feet and sustained other severe injuries. The hand was in extension, and the metacarpal bones of all the fingers were tilted into the palm, that of the thumb being slightly if at all displaced. Reduction was easily effected, and the ultimate result was good.

LUXATIONS OF THE PHALANGES have been observed in children. Hamilton mentions several cases in which the first phalanx of the thumb was displaced backward. Simpson[2] reports a case of dislocation of the same bone forward in a boy aged nine, by a fall on the hand; the head of the bone was grasped between the tendons of the flexor brevis, but was reduced under chloroform.

The symptoms are characteristic, and the indications clear.

Symonds[3] has reported two instances of dislocation backward of the first phalanx of the index finger, in boys aged nine; one was by a blow with a cricket-ball, the other by a fall. In each case he opened the joint and divided the retaining bands, with good result. It may be noted also that in each case the investing cartilage was fissured into the bone.

A number of additional cases have been recently reported by Dr. W. H. Battle.[4]

Compound luxations of the thumb- or finger-joints are not uncommonly met with, the end of the displaced bone forcing its way through the skin. Occasionally resection, or even amputation, may be indicated; but in the vast majority of instances, in children, if anæsthesia is induced and the bone put into place, the wound being made thoroughly aseptic, the result obtained is astonishingly good. At all events the attempt should be made, since even if it fails the delay will do no harm.

[1] British Medical Journal, April 8, 1882.

[2] Lancet, February 11, 1888.

[3] British Medical Journal, March 17, 1888.

[4] Annals of Surgery, 1889.

LUXATIONS OF THE HIP-JOINT rank next in frequency, in children, to those of the elbow. They may occur congenitally, either one or both joints being affected; but in such cases there is malformation, often if not always due to central nerve-lesion, and a special article will be devoted to their discussion.

Hamilton mentions a man named Warren, who had the power of luxating nearly all his joints at will, and says that this began in his infancy, by frequent accidental and spontaneous displacements of the hip. Two children of this man, a boy and a girl, had the same tendency to accidental dislocations of the hip. Stanley[1] saw a stout, muscular boy aged eighteen, who could displace the head of either femur upon the dorsum ilii and return it to the acetabulum again; this was no doubt a condition which had existed from early life.

Luxation of the hip may take place upward and backward, the head of the femur lodging upon the dorsum ilii; and this, in children as in adults, is most frequently the case. Or the head of the femur may go downward and backward into the ischiatic notch, or downward and forward into the thyroid foramen, or upward and forward, resting on the pubes or in that vicinity. An accurate idea of the mechanism in any special case in a child is rarely attainable, and, so far as my knowledge goes, the only dissections of recently-luxated hips have been in adults. From the anatomical conditions of the joint in childhood, it seems to me probable that the head of the bone may pass out of the socket directly, and not that, according to the theory held by H. Morris[2] and others, the rent in the capsular ligament is always at its lower part. Mr. Morris has, however, reported[3] the case of a boy aged seven, with a dorsal luxation produced when the limb was in abduction; so that here the bone would seem to have gone out below and in front, subsequently slipping up upon the dorsum.

A number of instances are upon record in which luxation of the hip has occurred without known cause, in children who have been the subjects of fever or of rheumatism. Stanley[4] gives an account of one such in a boy aged fourteen, who had had rheumatic fever, the hips having suffered; here the limb was everted, and shortened three inches and a half; the head of the bone was plainly felt under the glutei muscles. In all the other cases the luxation has presented the usual features, to be presently mentioned, of the dorsal luxation. Stanley mentions another case, in a girl aged fourteen, who, however, had a fall on the hip about six weeks before the displacement was noticed; reduction occurred spontaneously, but the bone was again luxated, and so remained. Verneuil,[5] in the case of a girl aged ten, with rheumatism following typhoid fever, reduced a dorsal luxation of the femur on the sixth day; a good result was expected when the report was made. Brown[1] reports the case of a girl aged eight, who had had an attack of rheumatism lasting three months and a half; she got up June 15, and a spontaneous dorsal luxation of the right femur was detected. She came under Dr. B.'s care October 4, when he accomplished reduction by manipulation. Langenbeck had one in a boy aged eight, who had had typhus fever; two months later, efforts at reduction failed. In several such instances excision of the head of the bone has been resorted to; as, for example, by Rawdon,[2] in a girl aged eight, and by Adams,[3] in a boy aged eleven.

[4] Ibid., 1841, vol. xxiv. p. 132.

[5] Bulletin de la Société de Chirurgie, October 31, 1883.

No doubt in some of these cases there has been so much inflammation as to have given rise to adhesions of the head of the bone to the neighboring parts. Hayward[4] mentions a boy aged eight whose femur became displaced on the dorsum nearly four months after typhoid fever, and another aged ten in whom the same lesion occurred just as he was recovering from scarlatina. In both instances the dislocation was permanent. A like result is reported by Franks[5] in the case of a girl of fifteen, the luxation having followed acute rheumatism.

Gibney[6] has recorded an interesting case of spontaneous dorsal dislocation of the hip, repeatedly recurring, in a girl aged nine, under treatment for acute disease of the joint at an early stage. At the time of the report, it is said, there was "no deformity, child free from pain, and case in every way doing well." Hilton[7] mentions three cases: a boy aged five and a girl aged seven, in both of whom ankylosis ensued; and a girl aged fourteen, in whom the left femur was luxated on the dorsum and the right into the foramen ovale, both being reduced with a good result. Ormerod[8] relates the case of a girl aged six, who had hurt her hip by a fall, and in whom the head of the femur became gradually displaced on the dorsum ilii, where it contracted firm adhesions; the ordinary symptoms of hip-joint disease would seem to have been absent.

The degree of violence producing traumatic luxations of the hip in children has varied greatly in the different cases on record; sometimes it is very severe, as a fall from a height, the crushing weight of a heavy door (in two instances), or the passage of a wagon-wheel over the hip. Sometimes a mere fall on the ground has been assigned as the cause.

Dorsal luxation is said to have occurred before the age of one year in a girl, seen by Gross when she was seven years old; the abnormal position of the head of the bone was then clearly to be perceived. South[1] states that in the case of a child "close upon one year old" reduction was effected by Stanley. Tracy[2] saw a boy aged twenty-two months in whom the lesion was caused by a fall from his nurse's arms; the bone was easily restored, with the aid of anæsthesia. The youngest case I have myself treated was a girl aged three and a half, brought to the Episcopal Hospital in 1881; reduction was easily accomplished by manipulation.

[7] On Rest and Pain, London, 1877.

[8] Clinical Collections, etc., p. 116.

The symptoms of this injury are adduction of the knee, which is drawn up over the opposite thigh, the foot being more or less closely applied to the instep of the other, and the whole limb seeming to be shortened; motion is limited and painful; the trochanter projects, and is higher than it should be, and the head of the bone can be felt as a hard mass above and behind the position of the acetabulum; a hollow is perceived beneath the sartorius muscle. Nélaton's line, from the anterior superior spine of the ilium to the front of the tuber ischii, crosses the trochanter below its tip, which it should just touch.

It would seem as if the diagnosis ought to present no great difficulty. Yet Norris[3] has reported a case in which a boy of twelve, at an early stage of disease of the joint, was supposed to have a dislocation, and was subjected to severe suffering for its reduction; and another in which a boy who had a dislocation was treated for some months with the idea that the neck of the bone was fractured.

Reduction is to be effected by manipulation, which should be very gentle, an anæsthetic having been given. The chief obstacle to be overcome is the resistance of the ilio-femoral ligament. Muscular contraction has very little to do with the matter. There is a rent in the capsule, through which the head of the bone has escaped, and through which it must go back unless such violence is used as to tear off any portion of the capsule which is in the way. We should never forget, in dealing with these cases in children, the delicacy of their tissues as compared with those of adults. The best rule is to flex the thigh upon the abdomen and the knee upon the thigh, next with moderate traction to adduct the limb, and then to rotate it outward into abduction. Pressure may at the same time be made upon the head of the bone by the fingers of an assistant; but this is not often called for. Sutton,[4] in the case of a boy eight years old, used a roll of cloth as a fulcrum in the groin, the limb being then flexed upward and rotated outward, with perfect success.

The head of the bone should be allowed to follow its easiest course; and the surgeon should never forget that the leverage exerted through the length of the femur is very great, so that he may by undue force cause a fracture. Such an accident, in the case of a boy aged fifteen, is recorded by Hamilton. Under the old plan of forcible extension by means of pulleys, there was perhaps even less danger of this, since there was less likely to be a twist impressed upon the bone; yet it did sometimes occur, as in one case under the care of Drs. Harris and Randolph,[1] in a boy aged twelve, and in another, that of a boy aged fourteen, related by Sir A. Cooper.[2]

[3] American Journal of the Medical Sciences, February, 1840.

[4] Western Journal of Medicine and Surgery, September, 1868.

An anæsthetic is not always indispensable. Ashhurst[3] has reported the case of a boy aged eight, with a dorsal luxation produced an hour before by direct violence, in whom manipulation was entirely successful, without ether.

Reduction is, however, not always easy, or even practicable. Hamilton saw a German aged nineteen who at ten years of age had a dorsal dislocation which Chelius the next day failed to reduce, and five or six later attempts by the same eminent surgeon were equally fruitless.

Reduction having been effected, it is, as a general rule, needful only to tie or bandage the little patient's knees together, and to keep him in bed for a few days, until all soreness of the parts has subsided. In one case, reported by Farrant,[4] a boy seven years of age sustained a dorsal luxation by a fall, another boy falling upon him; the bone was easily reduced by manipulation, and it is stated that the child "was running about at the end of six weeks." No details are given, but the recovery would seem to have been unusually slow, if there was no inflammation of the joint. Should inflammation ensue, it is to be treated on general principles. I know of no instances in which strumous abscess has followed an injury of this kind, although it has been spoken of[5] as a possible consequence, to be guarded against by absolute and long-continued rest. Gibney, in the case before quoted, found a carefully-fitted splint, made of Manilla paper stiffened with glue, effectual in overcoming the tendency to recurrence.

For one reason or another, it sometimes happens that these luxations are not reduced immediately after their occurrence. Hamilton mentions a case of Fanning's, in a girl aged two and a half years, and South[6] one in a girl aged six, in each of which the bone was replaced after ten days. Bigelow, in a girl three and a half years old, whose hip had been twelve days out, succeeded by manipulation, aided by manual pressure on the head of the bone. Anderson,[7] of Leith, in 1772, reduced by manipulation the hip of a boy aged eight, on the nineteenth day. Hilton,[8] in a boy aged five, made reduction by extension, one month after the receipt of the injury. Gibney (*loc. cit.*) succeeded in the case of a boy aged four, injured six weeks previously; and Lediard[1] in that of a girl aged five, after the lapse of eleven weeks. Fayrer[2] mentions that of a Hindoo girl aged six, who by a fall two or three months before had sustained a dorsal dislocation; the pulleys were employed, and the condition "relieved;" but it is said that "the cotyloid cavity appeared to have become obliterated."

[8] Lancet, March 12, 1853.

I believe the interval in Lediard's case to be the longest on record, in a child, between dorsal luxation of the hip and successful reduction. (One case has been reported in which reduction was claimed to have been effected without difficulty after the lapse of six months, in a girl aged thirteen; the other hip is said to have been also luxated, and the cervix fractured. The account is too incomplete to be accepted.)

Jones,[3] in the case of a boy aged eleven whose femur had been dislocated five months, after unsuccessful attempts at replacement, excised the head of the bone, with a most satisfactory result. Stimson mentions that in 1886 McBurney, having under his care a boy about seven years old, with a dorsal dislocation of several months' standing, made an incision, and divided the ilio-femoral ligament; he then reduced the head of the bone, which, however, became carious, and was excised some months later. The final issue of the case is not stated.

The possibility of the existence of unsuspected disease of the hip-joint should not be lost sight of in dealing with these cases. Bigelow relates a striking instance of the kind, in a boy thirteen years of age, who had a dorsal luxation of three months' standing, the reduction of which was followed by stiffening and the formation of sinuses; it then came out that the trouble was of much older date.

Occasionally, but very rarely, this luxation is complicated with fracture of the femur. Sir A. Cooper mentions an instance of this kind in a boy thirteen years old, the fracture being at the middle of the bone; the dislocation was not at first detected, and, when it was, "some attempts were made to reduce it, but the fracture would not then bear the extension," and the idea was abandoned. At the present day manipulation would, of course, be employed, and the chance of success would be much greater.

When the head of the femur is displaced into the *sciatic notch*, the symptoms are nearly the same as those of dorsal luxation, but the shortening and adduction are less, and the trochanter, instead of projecting, is rolled backward, while the prominence of the head of the bone is only obscurely felt in its abnormal position. Hamilton says he has adopted with advantage a suggestion of Squire's, to pass the finger into the rectum in order to feel the head of the bone from within; the case was that of a boy twelve years old, with a luxation of six months' standing.

(The reader is referred, for a fuller discussion of the varieties of hip-luxations than can be given here, to the essay of Bigelow "On the Hip," and to works on general surgery, in which Bigelow's views are reproduced.)

[2] Clinical and Pathological Observations in India, London, 1873, pp. 248–250.

[3] Lancet, November 15, 1884.

Reduction is effected by a manœuvre almost precisely the same as in the dorsal luxation; the sweep in circumduction is less, on account of the lower position of the head of the bone, which is nearer the acetabulum. Sometimes the effect is simply to change the ischiatic to a thyroid or to a dorsal luxation, and back again; in which case success may perhaps be attained by lifting the head of the femur outward, at the same moment making slight extension.

South[1] says that the younger Travers, in a case of sciatic luxation in a boy aged five, fixed the child's pelvis by strapping to a table, and turned him on the sound side; he then effected reduction by extension, with slight rotation outward, at the same time raising the knee. Ormerod[2] mentions a case in which a girl five and a half years old, by the fall of a bank of earth, had a luxation of the head of the femur into "the upper and back part of the sciatic notch." Manual extension was made by Mr. Stanley for two minutes, when the bone resumed its place, and remained there. Fenwick[3] found it easy to reduce a luxation of this kind ten days after its occurrence by a fall in running, in a boy aged four. Adams,[4] in the case of a boy twelve years of age, who by a fall from a horse a month previously had sustained a sciatic luxation of the femur, attempted to reduce by manipulation, but failed; the pulleys were then used, in vain; when a renewed trial of manipulation was successful.

Luxations of the head of the femur into the *thyroid* or *obturator foramen* have been repeatedly observed in children. Powdrell's[5] case, in a girl only six months old (the youngest upon record), was of this character, and was caused by the upsetting of the child in its little chair. Lisfranc[6] reduced, in a boy eighteen months old, a thyroid luxation due to a fall from the nurse's arms, the child's legs being widely separated. Hamilton mentions three cases, two seen by himself and a third reported by Warren, in which the head of the femur was only partially luxated forward, resting in the cotyloid notch; one was accidentally reduced, but in the others the displacement could not be rectified.

The symptoms here are eversion and lengthening of the limb; flattening of the hip; the presence of the head of the bone in its abnormal position; there is also a tendency to flex the body forward, in order to relieve the tense muscles of the thigh.

Reduction is effected by carrying the knee, still abducted, upward, so as to flex the thigh on the abdomen, then bringing it inward, and lowering it again in adduction, at the same time making slight traction and rotation inward. Hey[1] has recorded the case of a boy "whose thigh was reduced while he sat upright, and astride of the bedpost." From the other cases given along with this, it appears that extension and rotation were used, the bedpost serving as a fulcrum.

The replacement is sometimes very easy. Bryant says that in a girl of fourteen, who came under his care, the head of the bone slipped into the socket on simple flexion of the limb for the purpose of making the diagnosis. Ashhurst,[2] in the case of a boy ten years old, reduced without anæsthesia a thyroid luxation of several days' standing. Fayrer[3] reduced one in a Hindoo boy aged six, by manipulation.

Occasionally more difficulty has been encountered, especially under the old methods. Ormerod[4] cites a case in a boy aged five, under the care of Mr. Vincent, in which the head of the bone was supposed to be in the thyroid foramen. There was eversion of the foot, and serious interference with the circulation. Extension was tried without effect until the thigh was well adducted, when the head of the bone slipped into place at once.

Sir A. Cooper gives a rather vague account of the case of a boy sixteen years old, the subject of thyroid luxation, in whom, during efforts at reduction by "extension of the superior part of the thigh perpendicularly," the head of the bone passed into the sciatic notch, where it remained. Hamilton refers to the possibility of such a change during manipulation.

Williams[5] has reported the case of a boy eight or nine years old, who came under his care five months after he had sustained a luxation of the left hip, probably thyroid. Reduction was effected, but there was great difficulty in preventing the recurrence of the displacement, until a block of gutta percha was shaped so as to embrace both hips.

In the Warren Museum[6] there is a photograph of a little girl six years old, who had a thyroid dislocation of four years' standing. The hip and knee were strongly flexed, and the limb everted, wasted, and useless. An attempt was made at reduction, the rectus femoris muscle and fascia having been divided; but a partial fracture at the middle of the femur resulted. This united well, and "by the use of extension and other mechanical means" the condition of the limb was greatly improved.

Cooke[7] has reported the case of a boy aged nine, who got his right leg in a hole, his knees being wide apart; the result was a thyroid luxation, and a green-stick fracture just below the trochanters; reduction was effected, and the fracture set, the boy making a good recovery.

[7] Lancet, January 9, 1864.

Compound luxation of the head of the femur upon the thyroid foramen, in a boy aged twelve, has been reported by Woodward.[1] The boy was caught and rolled over and over under a moving car; the bone projected out over the scrotum, and was entirely denuded. Very little bleeding took place. Other severe injuries were sustained, and death ensued from shock in about five hours. Another fatal case, in a boy aged fourteen, is quoted by Stimson from Macouchy; I have not access to the original account.

Sometimes the head of the femur is displaced forward and upward. In a boy aged nine, whose case is reported by Barker,[2] it rested just above the acetabulum and below the inferior spine of the ilium; the trochanter was turned backward toward the sciatic notch; the limb was abducted and somewhat everted. Reduction was effected by the usual manipulation, but with rotation inward. The boy had fallen while trying to jump on the back of another boy; he walked about for six days before coming under treatment. I have lately had in my wards at the Pennsylvania Hospital a young man of twenty-three, who at the age of ten fell from a trapeze, and sustained an infra-spinous luxation of the left femur, which still remains unreduced. There is neither inversion nor eversion of the foot; the limb is shortened about an inch, and atrophied; and the acetabulum, which can be felt, seems to have been filled up by bony or fibrous deposit.

Erichsen mentions that he saw a luxation of the head of the femur on the pubes, in a child eighteen months old; but gives no further details. Bryant[3] says that he saw his colleague Mr. Birkett "reduce, with the greatest facility, a dislocation of the head of the femur on the ramus of the pubes in a boy aged twelve, when the femur was broken below the trochanter; the bone slipping into place on the application of gentle, well-directed force."

An extraordinary case has been reported by Scriba,[4] in which a boy thirteen years old was knocked down backward as he stood with his left foot far back, and his legs wide apart. The head of the femur was sunk into the iliac fossa beneath the vessels and nerve, the cervix resting on the edge of the pubes. Of course the head of the bone had to be lifted out of its position and brought down in front of the pelvis, when it was reduced by the usual manipulations, with extension.

LUXATIONS OF THE KNEE-JOINT, rare in adults, are still more so in children. We do indeed, as a result of degenerative inflammation of the joint, often find the relations of the tibia to the femoral condyles more or less changed; but such displacements may be best considered in connection with the joint-diseases to which they are due.

Cases of congenital luxation—or, perhaps it would be more correct to say, of abnormal mobility—have been recorded by Wutzer,[1] by Kleeberg,[2] by Gueniot,[3] and by Barth.[4] In Wutzer's case, as in Barth's, and in one seen by Hamilton, the hips also were abnormally movable; in the former the patellæ were absent in front, but there were bodies at the back of the joints, firmly attached to the femora, which were thought perhaps to be their rudiments, misplaced. Gueniot reported two cases, and quoted seven others; in the discussion the propriety of the term "luxations" as applied to them was questioned by Lannelongue and Sée. The abnormity consisted here, as in a case reported by Bard[5] and in another by Youmans,[6] in a flexion forward, or more properly an excessive extension, of the leg on the thigh. In Youmans's case the patella was smaller than that of the sound limb.

Hamilton records a curious case in which a boy ten years old was struck on "the top of his knee" by the head of a playmate, with the effect, it would seem, of forcing the condyles of the femur backward; the luxation is said to have been only partial, and was easily reduced by extension and pressure; it was followed by violent inflammation, but eight weeks afterwards "the motions of the joint were nearly restored."

Bulteel[7] met with a case of rotation of the tibia outward and forward, so that the toes were everted, in a boy twelve years old, who received the injury while "skylarking" with a friend; the knee was semi-flexed, and was easily reduced by flexing it completely; no inflammation ensued.

Bagnall-Oakley[8] has reported his examination of a man aged seventy, who at the age of nine months had been let fall from his aunt's arms; either by this violence or by the resulting inflammation his left tibia was luxated backward on the femur, with which it had formed a false (new?) joint; he had always had full use of the limb, and flexion of the knee to perhaps fifteen degrees.

The alteration in the shape of the part, the limitation of motion, sometimes the position of the foot, together with the history when attainable, should prevent any mistake in diagnosis.

No very great displacement can occur without tearing of the lateral, and perhaps of the crucial, ligaments; and the ensuing inflammation may be such as to involve the loss of motion in the joint, or even graver results. Hence a guarded prognosis will always be given in such a case by a prudent surgeon.

As to the treatment, no definite rule can be laid down. The essential points are to restore the normal relation of the bones, and to prevent or allay inflammation by suitable measures.

Compound luxation of the knee-joint is an accident of the greatest gravity. Yet Forster[1] gives the following account of a case which occurred in a child five years old. "So serious was the injury that amputation was decided on; but the boy was too ill to bear the operation. The dislocated bone, therefore, was reduced; in time, perfect ankylosis occurred, and the child recovered, with a stiff joint."

Stimson mentions a case in which "a boy eleven years old suffered a compound dislocation by having his leg caught between the spokes of a wagon-wheel;" but he does not refer to it further.

The patella may be luxated by violence, or by muscular action, or by both combined; the mechanism can rarely be determined with accuracy. Such displacements have been repeatedly noted as congenital, or as the result of disease.

By far the most usual form of this lesion is that in which the bone passes outward, slipping over the front of the outer condyle of the femur. Or it may be rotated upon its axis, so as to rest upon its inner edge.

One of my own children, at the age of nine, was thrown down while playing, and could not rise; I found him with his left knee flexed at a right angle, immovable, and the patella resting on the outer condyle; in the act of inhaling ether he struggled, and the bone slipped into place. Bradner[2] has recorded a very similar case, also in a boy aged nine; the patella was "set up on its inner edge;" the knee was slightly flexed; reduction was effected by raising the foot and depressing the knee, which was thus over-extended.

Sometimes loss of power, by injury, of the vastus internus allows the vastus externus to pull the patella outward, as in a boy aged eleven, of whose knee there is a cast in the Warren Museum.[3] Here the dislocation was permanent. In another instance, reported by Roux,[4] in a girl aged thirteen, it was due to rupture of the aponeurosis at the inner side of the joint; it was habitually recurrent, and was cured by dividing the vastus externus, and by shifting the attachment of the ligament of the patella toward the inner side of the tibia. Golding-Bird[5] has recorded a case in which the vastus internus seemed to have been paralyzed by a fall, in a girl aged eleven. Godlee referred to another case in a boy aged six.

Cases in which this luxation was due to infantile paralysis have been reported by Pitts[6] and Allingham.[6] Lannelongue[7] and Prewitt[8] have met with instances in which it was congenital. In Prewitt's case both patellæ were above and at the outer side of the outer condyle of the femur, and the toes were webbed.

Luxation of the semilunar cartilage has been observed in a few cases in children; but it presents no special features in them, and need not be discussed here.

[8] St. Louis Courier of Medicine, April, 1882.

Luxation of the head of the fibula backward is reported by Richardson[1] in a boy aged nine, who fell from a fence, striking the knee; it was easily reduced, and kept in place by a bandage. Oldright[2] saw a case in a boy two years old, who fell from a chair; at the time of the report, the bone could not be kept in place. Another instance in a child sixteen months old, by direct violence, is mentioned by Rosenberry;[3] but no details are given.

A mistake in diagnosis can hardly be made in a case of this kind. An important indication in the treatment would seem to be the fastening of the foot in inversion, so as to get the leverage of the whole bone to keep the upper end in place.

LUXATION OF THE ANKLE has been compound in all the cases known to me in children. Sir Astley Cooper cites two cases, in boys aged thirteen years, one seen by Ormond and one by himself; and Parrott[4] has reported one in a boy aged eleven. In all it was the result of great violence, and the necessity of amputation seemed imminent. In Ormond's case, although reduction was effected, the external malleolus and "a broad portion of the articulating surface of the tibia" exfoliated. In Sir A. Cooper's case the end of the fibula was broken off; it was removed, and half an inch of the lower extremity of the tibia was sawn off, before reduction could be made. A good result was, however, obtained in each instance. Bryant says that he treated a boy aged twelve in whom both the bones of the leg protruded through the wound, which was washed, the luxation reduced, and "a sound recovery ensued, with a movable joint."

Amputation has been unavoidable in the few cases of this kind which have come under my own care.

LUXATION OF THE BONES OF THE FOOT is extremely rare in young subjects. Liston[5] mentions the case of a boy aged fourteen, who fell a distance of forty feet, striking on the end of his foot; the scaphoid and cuboid bones were forced upward out of place, and could not be reduced. He mentions another boy, also fourteen years old, who by a fall from a horse sustained a compound luxation of the distal end of the metatarsal bone of the great toe, breaking it off; it was removed, and he made a good recovery. I have recently had in the Pennsylvania Hospital a boy twelve years old, who was caught under a street-car; the left foot was strongly inverted, and it was found that the scaphoid bone was partially displaced upward; reduction was effected with difficulty, and could only be maintained by keeping the leg and foot bandaged so as to force the latter outward. Complete recovery ensued.

SYNOVITIS—ARTHRO-MENINGITIS.

By A. J. STEELE, M.D.

THE synovial membrane occupies anatomically a middle ground between the serous and the mucous membranes. It is exceedingly delicate, and may not, like the capsule of the kidney, for example, be peeled off from its attached surface,—is not a firm individual structure, but a mere covering for the ligamentous structures and tendinous expansions surrounding the articulation, its free surface looking towards the interior of the joint. As, however, it passes from one tissue to another it retains its peculiarity,—namely, connective tissue containing numerous vessels and nerves, with a free surface of irregularly branched connective-tissue corpuscles, here and there collected in patches presenting the appearance and, quite likely, partaking of the true character of endothelium. The cells of this endothelial layer are held together by an albuminous ground-substance.

Physiologically there is a resemblance to the serous membranes in the secretion of a lubricating fluid—synovia—to diminish friction between two movable surfaces. A similarity is also observed in these membranes in their alike rapid response to irritation, resulting in an inflammation, formerly dreaded by the surgeon, but now, under antiseptic precautions, little feared.

The synovial membrane is a tissue of high vitality, and, on account of its great vascularity, is more prone to inflammation, to intense reaction from slight irritants, than the other joint-structures. It is sensitive to disturbing causes, whether injury received from without, or poisons or irritants brought to it by the blood. All cases of inflammation of this membrane do not run the same course: they differ in degree and are attended with different results. These differences depend upon the severity or virulence of the disturbing cause, as also upon the condition of the general system,—the activity of the seed and the character of the soil.

The degree of inflammation and its results determine the name that is applied to the individual case or to the class of cases. Thus, with the inflammation low and attended simply with an increase in the synovia or serum within the joint, it is designated *simple synovitis* or *sero-synovitis;* with a more intense inflammation present, so that corpuscles are thrown off, leucocytes and endothelial cells, rendering the increased synovia turbid, pus-like, it is termed *purulent* or *catarrhal synovitis.* This is yet a surface inflammation; but, the action becoming still more intense, involving not only the synovial but also the subsynovial and perisynovial structures, so that pus comes from the deep tissues, and attended with a real disintegration, it is termed *suppurative synovitis;* which going on unchecked draws into the destructive process other structures of the joint,—cartilage, bone, ligament,—and thus becomes a veritable *arthritis* (*panarthritis*). On the other hand, there may result a new formation of tissue, *hyperplastic synovitis,* and a *fungous synovitis,—strumous* of some authors, *tuberculous* of others.

It is pertinent to inquire here if all these forms of joint-trouble are found in the young. While replying in the affirmative, it may be observed, in addition, that there is a difference between the articular inflammations of adults and those of children. In the former the inflammation tends to remain localized in the tissue first affected, and to retain its essential pathological character; whereas in the latter it tends to spread to other structures or to assume a different character. For example, a simple synovitis in the adult, even though severe and assuming great dimensions, remains the same original process; whereas in the child it may rapidly disappear, under proper treatment, or may take on a hyperplastic form, or may change to a fungoid inflammation gradually spreading to the other joint-tissues. The cause of this difference is to be found in the rapid tissue-change of childhood peculiar to growth, in the greater plasticity of tissue, and in the proneness of local disturbances to be modified and affected by general or constitutional conditions and taints. The adult's tissues are fixed, resistive; the child's, rapidly changing, vulnerable.

An arthritis does not find a starting-point in disease of the cartilage or ligament: it begins in the membrane or in the bone. Childhood is prone to osteitic inflammation, especially in the joint-ends: such cases do not concern us here except so far as the membrane becomes secondarily affected: then the clinical features run a common course, which will be duly considered farther on.

PATHOLOGY.

In *simple* (*sero-*) *synovitis* the membrane becomes congested and œdematous, and the fimbriæ swollen, blood extravasations occur here and there, and the contrast becomes marked between the bright red of the membrane and the pearly white of the cartilage. Leucocytes escape and reach the interior of the joint, serum is poured out, or, if the action is intense, plastic exudation takes place. The endothelial cells multiply, and are cast loose into the joint even before they are fully developed.

The synovial fluid is increased in amount and becomes greatly diluted with serum; from clear it changes to light yellow and red, and is viscid and sticky. A slight mixture of cell-elements, endothelial cells and leucocytes, and fibrin-flakes, is found. If the process now retrogrades, the cell-proliferation ceases, the serum is absorbed, the enlarged vessels diminish, succulent tissues contract, and the normal condition returns.

This would be the picture in simple acute synovitis in the adult, and may take place in the child, but more likely in the latter the process progresses and intensifies. The leucocytes and cells collect in such numbers that the synovia becomes milky, almost pure pus; the inflammation is still limited to the membrane and subsynovial tissue,—is still, so to speak, superficial,—and is designated *purulent* (*catarrhal*). But if the process advances, the cartilages are involved, thicken, become cloudy and yellow, and later are eroded, laying bare the bone, the surface of the epiphysis is destroyed, and extensive ulceration and joint-destruction follow,—*suppurative synovitis.*

While in the child these destructive changes follow one another rapidly, yet they may, though rarely, be arrested at any one point, and if this arrest occur in an early stage restitution may be complete, or the change may be into the hyperplastic form.

It may be observed that a purulent synovitis following wound of a joint admits of a better prognosis in youth than in adults.

The specific fevers, especially typhoid, and rarely small-pox, are occasionally followed by arthritis, generally monarticular synovitis, or the cartilages and ligaments may be involved, producing much stiffness. Following typhoid the hip-joint is the one most generally attacked. After scarlet fever many joints may be affected; the same result has been observed to follow mumps, dysentery, and measles. If suppuration occurs it is confined to one joint. Rheumatic synovitis may also be included under this general division. In all these cases the process rapidly retrogrades under proper treatment, or results in a simple hyperplastic thickening of the membrane, with shrinking and fixation of the joint.

How it happens that the joints are affected in these specific fevers is a question yet *sub judice;* it is, however, likely that during the course of the primary disease some centre of infection is established from which septic material is absorbed.

When a synovitis is lighted up by the breaking through into the joint of pus from a bone-abscess or a neighboring periostitis, the advancing destructive process is very rapid, a panarthritis is produced which the most heroic therapeutic measures will scarcely arrest, and, in short, it may become a question not merely of saving the joint, but even of saving life.

The synovitis which in its results is hyperplastic in character may be simply benignant, or a destructive fungus; the former is rare in children, though, as already hinted, it may follow the infectious diseases or rheumatism as a polyarticular trouble; the latter as a fungous or strumous synovitis is an essentially different process. Here is formed a granulation-tissue, soft, spongy, rich in vessels and cells, interspersed with small yellowish papules which contain giant cells rich in nuclei, giving to the papules the histological character of miliary tubercle. The membrane becomes swollen, opalescent, and succulent, is loaded with exudation-products, and its surface assumes the appearance of granulation-tissue. The membrane continues to thicken, becomes soft and friable, and contains masses of caseous material. Later suppuration occurs. If not arrested, the inflammatory process extends to the joint-cartilages, ligaments, and bones, and a veritable panarthritis results.

If these cells are miliary tubercles, the interesting question arises, whence came they? Could it be from thickened, cheesy points of inflammation in the immediate neighborhood of the joint,—for example, in the epiphysial ends of the bones? This fungous inflammation does not partake of the character of a simple hyperplasia, but rather of that of a neoplasia, the tendency of which is to spread out on all the histologically different tissues of the joint and in the neighboring connective tissue; so that in place of the normal outlines of the joint there is to be found a thickened firm mass,—"white swelling."

It is this peculiarity that makes the affection so intractable, so dreaded by the surgeon, for he knows not where he may arrest it.

It may be difficult, in any given case, to determine whether the fungous (tuberculous?) process originates in the synovial membrane, in the intercapsular ligament,—teres or crucial respectively,—in the interarticular cartilage, or in a single cheesy point in the epiphysis, whose rupture infects the cavity of the joint. But observations of many cases in different stages of development throw the weight of opinion decidedly in favor of the latter as being the more common.

When commencing in the synovial membrane, the fungoid disease appears like a circumscribed tumor, which in the early stage interferes but little with the functions of the joint; it is only later that a general implication of the articulation occurs.

In the primary bony forms the process appears to begin in the neighborhood of the cheesy osteitic point, and extends gradually towards the joint-end, rupturing near the place of duplicature of the capsule or through the cartilage into the cavity of the joint. In the one case the process can remain localized for a relatively long time, can spread upon the perisynovial tissue, can ulcerate, burrow, and form fistulæ without involving the joint *in toto;* in the other case the course is acute, the total implication of the joint being well marked by the clinical features.

The fungous mass ulcerates and breaks up, pus forms, the cartilage softens and disappears, the ligaments soften, the bones become carious, "surgical fever" is present, and the case is critical as regards not only the integrity of the joint, but even the life of the patient. Fungous synovitis does not necessarily lead such a galloping, destructive course. It may under wise treatment, in a case of not too thoroughly depraved constitution, be arrested in any period of its course,—in the earlier stages with motion, in the later with ankylosis.

SYMPTOMATOLOGY.

Simple synovitis declares itself by pain, moderate at first, but increasing in severity, especially at night; by swelling of the joint within the boundaries of the capsule, indicated by fluctuation; by heat of surface in the superficial joints; by redness of skin in severe cases; by atrophy of contiguous muscles; by position of the joint, usually flexion,—"position of greatest ease;" and by limited or arrested motion. If the attack is quite acute these signs may be marked; otherwise some of them may be obscure and come on slowly. The child complains of a feeling of weariness and uncertain, nagging pains, which may be relieved for some time by quiet and position, or be aggravated by much motion. In the morning the joint will be stiff, in the evening more movable, but painful, hotter, and more sensitive to pressure. This condition drags along, the symptoms slowly increasing in severity until possibly sharply circumscribed points of pain lead to the suspicion of bone-involvement.

The forms of synovitis following the infectious diseases, in the likeness of acute joint rheumatisms, are indicated in the joints affected by markedly increased surface-heat, sensitiveness from the beginning, swelling, the skin red and shining, and the joint held motionless. The attack may be polyarticular, one joint after another becoming successively involved, skipping so rapidly that great swelling does not occur in any, though the pain is marked.

Rauchfuss has given us the symptoms of a sero-purulent synovitis that attacks infants, in which the exudation develops rapidly and may in a short time take on a purely purulent character. In the beginning the child is feverish and restless; examination of the nude body discloses immobility of one or more limbs and great sensitiveness to the touch. After twenty-four hours the skin over the affected joint, if superficial, like the knee or ankle, becomes red. If a deep joint, like the hip or shoulder, is the one involved, several days may supervene before the exudation can positively be demonstrated. The affected joints during this period assume certain fixed positions: the hip and knee flex, while the arm is drawn to the side of the chest. With care, fluctuation can be recognized in and about these joints. If in this stage the joint is emptied by puncture or tapping, motion becomes freer, and the pain and fever lessen, but the fluid reaccumulates rapidly, so that on the same day there may again be found the redness and tension. When the emptying is repeated daily with all due precautions, the exudation loses gradually its blennorrhagic character, appears more serous and more fluid, pus-cells undergo fatty degeneration and break up, and after many days the secretion disappears and the function of the articulation is restored. In very young children one or two timely openings bring the process to an end; in protracted cases the cure may take a longer time, or the process may come to a bad ending through ulceration of the cartilage, destruction of the epiphysis, rapidly-fatal meningitis, etc. Superficial cartilage once destroyed may be entirely restored through the active growth of these parts in infancy, and putrid discharge of the secretion is usually well borne by children.

There is a synovitis secondary to neighboring bone-disease, caused either by contiguity of the inflammation or by the products of the bone-disease breaking into the joint-cavity and as a local irritant inducing the disturbance. In acute osteo-myelitis the passage of pus into the joint occurs in the later stages, and is marked by an exacerbation of the symptoms,—increased pain and swelling, and elevation of temperature. In chronic osteomyelitis the neighboring joint is enlarged, the membrane is thickened, and there are acute exacerbations of pain and swelling as from time to time pus finds its way into the joint. A seasonable tapping assists in the diagnosis and becomes an admirable therapeutic measure. In circumscribed osteitis of the joint-ends of the bones the articulation is enlarged, with serous effusion, but is not especially tender or immovable, but when the pus has made its way into the cavity acute joint-irritation, with fixedness and aggravation of all symptoms, is produced.

Acute suppurative synovitis is known by the rapidity and severity of the symptoms, especially if septic matter has been carried into the joint by wound of the capsule. A traumatism may induce a serous synovitis, which under appropriate therapeutic measures subsides, or under adverse circumstances may advance to suppuration, which would at once be indicated by a high temperature. The more severe outcome is less likely to happen in children than in adults.

The hyperplastic proliferating synovitis, at times following the infectious diseases, at other times rheumatic in character, attacks several joints with the signs of acute exudative arthritis. The inflammatory conditions only partly disappear, leaving a thickening of the joint, doughy in character, admitting only of limited painful motion. The joints become flexed and retain abnormal positions, even after the inflammatory action has passed; the capsule shrinks, and the soft parts contract and adapt themselves accordingly.

The symptoms of strumous or fungous synovitis develop slowly, indicative of a subacute process. Usually some advance has been made in the affection before the physician's attention is called to the case. Impairment of motion, stiffness, lameness or limping, occasional pain, increased by passive movement, tenderness on firm pressure, uneasy sleep, with an occasional night cry, are present in the early weeks or, it may be, months. Without early recognition of the gravity of the affection and correct treatment, the case passes on into one of those chronic joint-diseases with which all are so familiar in children, happily less frequent now than formerly, because earlier recognized, better understood, and more rationally treated. In the examination, if the corresponding limb or joint is compared with the affected one, the muscles of the latter will be found by circumferential measurement atrophied, an important diagnostic point, always present to a greater or less degree. The wasting is greater and more rapid when the disease is grave, slight and slowly developed when still mild. This atrophy of the neighboring muscles causes the joint to appear relatively larger, the contours are changed, depressions are rounded out, and a boggy sensation is imparted to the touch. The swelling is less evident in the deeper-lying joints, as the hip and shoulder, but in the superficial articulations will be demonstrated without difficulty. In advanced disease much of the swelling will be due to infiltration of the surrounding parts and probably to abscess. The amount of pain is variable: it may be so slight as to mislead, and again may be a constant and distressing symptom from the beginning; it is usually increased by exercise of the part, and frequently causes the patient to cry out at night. Limitation of motion is present even from the inception of the disease, and becomes more marked as it advances. Flexion may be possible, but complete extension is rare, and rotation is greatly impeded. The former practice of giving an anæsthetic in determining the presence of joint-disease is to be deprecated. It was once thought that unless under its employment grating of the joint-surfaces could be detected no disease was present; we now know better, and, further, that it robs us of one of the most sensitive indications of articular trouble,—namely, reflex muscular contraction. By obtaining by gentle means the confidence of the patient, by manipulating first his sound limb, thus drawing his attention from the affected one, and by the use of tact in managing the frightened or angry child, resort to chloroform will never be found necessary. Definite positions are assumed by the different joints, usually that of flexion; naturally, the patient holds the limb in the position of greatest comfort; and certain groups of muscles are doubtless excited to reflex contraction more strongly than others. Slightly-increased heat is detected in the superficial joints. As the disease advances, enlargement and softening will indicate the presence of pus. Throughout the disease a diurnal (evening) rise of temperature will be noted, more marked in the later stages. The appetite fails. Pallor of skin and general wasting of body, with disturbed sleep and irritable temper, are present. If an abscess opens, flaky pus escapes. Night-sweats and diarrhœa may supervene. Amyloid degeneration may attack the glands, or tubercular meningitis may complicate the case.

ETIOLOGY.

The cause of simple or sero-synovitis may be local injury, a blow from without, a wrench within, fatigue from long exertion, or exposure to cold and wet: often the cause cannot be assigned. If early recognized and properly treated, the inflammation will subside; otherwise it will run on into a chronic state and possibly assume a hyperplastic form. In girls at the catamenial age it has been observed that with a cessation of the menses a serous synovitis ensued.

Joint-affections are sequelæ or concomitants of the exanthemata,—scarlet fever, typhoid fever, small-pox, etc.,—one or more articulations being affected; the same after measles, dysentery, and mumps. Pus very rarely forms. As already suggested, some centre of infection in connection with the general disease furnishes septic matter for absorption, which lights up local inflammation in the joint. Some hold to the theory that the cause is a specific poison circulating in the blood.

It is difficult to find sufficient cause for the sero-purulent synovitis that occasionally attacks young infants. An explanation has been sought in the bowel-troubles incident to that age. It is monarticular in character, and attacks by preference the shoulder, the hip, or the knee. The cause is more readily understood when a local inflammation in the form of an osteitis of the neighboring epiphysis is lighted up, due to blood-poisoning, or to injury during or soon after birth, or to an osteo-myelitis of the bone-ends in older children, strumous or syphilitic in character or due to local injury or to exposure to cold and wet. Here from contiguity of the inflammation the joint becomes involved, and later when pus breaks into the cavity severe and marked symptoms suddenly manifest themselves.

We seek for the cause of fungoid synovitis in a constitutional dyscrasia with some local injury to determine its expression in the individual joint. A traumatism—blow, fall, wrench—can usually be traced. It is, however, the constitutional peculiarity that gives the characteristic history and expression to the disease. For lack of a better term, this systemic condition is styled strumous or scrofulous: it consists in a defective state of the general health, with a tendency to chronic inflammation of certain tissues, leading to fungous growth, suppuration, and caseation. This state of the health may be hereditary or acquired,—tuberculous as an example of the former; impaired health from precursory acute disease, or from poor food, vitiated air, dark, damp dwellings, as examples of the latter. That scrofulosis and tuberculosis are one and the same cannot yet be admitted; that they are allied must be acknowledged; possibly the former is a stage or degree of the latter; certainly they have much in common, so that we are not surprised to find the tubercle-bacillus in the hyperplastic tissue of advanced fungous synovitis. While, as a rule, a constitutional cause may be found for the local affection, yet in children apparently free from any taint or ill health the joint-trouble may develop, and, as previously hinted, a neglected simple synovitis may advance and change into a chronic fungous condition, with suppuration and destruction of the joint. The joints of the inferior extremity are more frequently found diseased than those of the upper. How else can this be accounted for than by the fact that they are more subject to trauma from concussion in running, jumping, and falling? If general or constitutional cause had all to do in their production, this difference in frequency between the upper and the lower limbs would not exist. We are thus forced to believe in a constitutional impairment as a predisposing cause, and in a local injury as an exciting cause. In the matter of predisposition, it must be admitted that breathing vitiated air (it may be from house-furnaces), living too much in-doors, eating too rich food, with late hours and nervous excitement,—all these, even among the well-to-do classes, would undermine the health of the young. It can be readily understood why in the earlier years of life, while active tissue-change is going on in the joints,—in the cartilaginous epiphysial bone-ends,—transition from the fœtal to the adult forms,—the articulations should be so vulnerable to local injury.

THERAPEUTICS.

The sheet-anchor in the treatment of all joint-diseases in children is rest to the inflamed articulation. When the inflammation is arrested, motion may be permitted, but not until then. Rest in the beginning, in the middle, and at the ending of the diseased process should be the therapeutic maxim. Oftentimes the problem concerning us most is how best, by what appliances, to immobilize the joint. The ingenuity of surgeons has been taxed to supply an apparatus that would do this and yet not interfere too materially with what was necessary in the way of obtaining fresh air, sunlight, exercise, to the improving of the general condition. At the very outset it is necessary to keep in mind the importance of rest and position to an inflamed joint; doing so will materially simplify our therapeutics.

In acute simple synovitis the limb has naturally taken the position of greatest ease, but this is not always the position of greatest usefulness should, unhappily, the joint become stiff. To extend or otherwise place the joint in the best possible position should very early be the aim of the surgeon,—by gentle measures if possible, under anæsthesia if necessary. Ordinarily the rest and relaxation afforded by an efficiently supporting splint cause the muscular rigidity to subside, so that the limb can after a few days be placed in an improved position. Leather, metal, felt, gypsum, or pasteboard splints may be used, and additionally in the upper extremity a sling: in the lower limb the weight of the body should be taken off the joint by adopting the horizontal position. Elevation of the limb lessens the amount of blood-tension in the joint, and evaporating lotions or cold-water irrigations will help to reduce the inflammation, if high. Equable pressure, attained by enveloping the joint in prepared wool surrounded by rubber bandage, will hasten absorption of the secretion; if, however, the latter persists, aspiration of the joint under antiseptic precautions will afford marked relief. Later the hardness and stiffness may be removed by massage and douching. Iodine, in the form of tincture to which a little glycerin has been added, or the compound ointment, may be applied externally. Care must be exercised in the employment of blisters in the young.

In the way of general treatment, if fever exists, half-drop doses of the tincture of aconite may be administered every hour or two until the pulse is reduced, and morphine injections or Dover's powder by the mouth until the pain is relieved. Milk broth and farinaceous diet should be given for a time. So long as pain or heat exists in the joint, the immobilization should be continued. Again reference is made to the importance of not moving the joint until all inflammation has subsided.

Suppurative synovitis and arthritis require prompt remedial measures: thorough immobilization and support to the joint and limb by a splint so arranged that access to the joint can be had; in the acute stage cold to the articulation, and aconite internally. Marked fluctuation in the joint would suggest aspiration, which is often attended with great relief of symptoms.

If pus is detected, free opening of the joint under antiseptic precautions, with efficient drainage and antiseptic dressings, will afford relief and give a favorable turn to events. If pus appears in another part of the joint, it, too, must be evacuated. It has been suggested that instead of employing the knife, objectionable on account of hemorrhage, the trocar be used, and that if matter reaccumulates the second tapping should be done in the same spot as the first. If the opening of the joint has been too long delayed, so that the case is going on from bad to worse, if the joint becomes disorganized, and profuse suppuration continues, with burrowing of matter, and the general health is giving way, with loss of appetite, and high fever, amputation must be considered, and promptly performed if deemed advisable.

The acute purulent synovitis of infants usually demands prompt emptying of the joint with the aspirator or the trocar, to be repeated as required.

Synovitis secondary to neighboring osteo-myelitis or periostitis requires for effectual treatment removal of the cause, in addition to the special treatment of the joint-complications, conducted on general principles, with punctures and immobilization. So, too, in the joint-troubles following pyæmia and the exanthemata, rest and support, and, when matter is confined to the joint, tappings; but if pus has escaped from bursting of the capsule into the surrounding tissues, free opening, with drainage, will be necessary.

Of all the forms of synovitis, that which interests us most as regards therapeutic management is the fungoid or strumous, because it is so common, so chronic, leads to such untoward results as to permanent maiming and as to life, and because differences of opinion yet exist among surgeons as to the best means to be employed for its relief. The term fungoid would indicate the presence of a material which should be modified, destroyed, or removed that a favorable issue be attained in the treatment: so, very naturally, injection of antiseptic agents into the joint was thought of and employed. Most commonly carbolic acid has been used, from a two-per-cent. solution up to a thirty-three per cent. and a fifty per cent. concentrated, eighty centigrammes to each injection of the former, repeated as high as fifty-two times, and twelve to twenty-five centigrammes of the latter. Iodine also has been employed for the same purpose. Favorable reports on the use of both of these agents have been given by some experimenters. On the other hand, such poor or negative results have been obtained by others that the method is as yet far from being universally accepted. For a time good results would seem to follow, yet they were not permanent. Further observations in this direction are necessary before we can advise resort to antiseptic injections as a therapeutic measure.

Late in the disease, when all hope is past that mild measures will arrest the progress of the destructive changes, resort may well be had to the removal of the fungus, now doubtless tuberculous, by heroic measures, such as opening the joint, scraping with the spoon, and clipping with the scissors, thus thoroughly removing all the diseased tissue, under antiseptic irrigation and dressings. But one hesitates to resort to such extreme measures until simpler means have been tried to alleviate the disease. Such simpler measures should be, as already suggested, immobilization of the joint, and, in addition, in some instances, counter-irritation and compression; for the former iodine, tincture or ointment, for the latter mercurial plaster in strips, or preferably the elastic bandage. But if, as previously suggested, there exists constitutional involvement in this disease, it, too, merits attention, and correction as far as may be, by the use of good food, fresh air, bathing, sunlight, and exercise, and for medicine the hypophosphites, with malt and cod-liver oil if borne.

In the joints of the upper extremity this indication of local rest can readily be fulfilled, the splint being best made of leather or felt, as being light, moulded over the part or preferably over a gypsum cast. By immobilization is not meant intermittent fixation: it must be thorough and constant. At no time after the inception of the treatment should the joint be moved, otherwise granulations may be torn and slight hemorrhages result.

In the inferior extremity the articulation may be prevented from bending, but additionally it will be necessary to prevent the concussion incident to weight-bearing. The ankle and knee can be efficiently fixed by firm leather splints, lacing at the side or in front, and the weight of the body taken from the limb by crutches, with a patten on the opposite boot; or the ischiatic crutch-splint of Mr. Thomas will meet both indications, though uncomfortably worn by some. In the hip-joint a strong pathological factor to be overcome is the contraction of the muscles, giving an abnormal posture to the limb and aggravating the joint-pressure. Extension by stirrup, weight, and pulley in horizontal position will readily overcome these symptoms, give the limb its most desirable position, ease the pain, and immobilize the joint if the trunk is kept supine. If one plans to carry a case of hip-joint disease to a successful issue by this method, not only the extremity but also the body should be tied down; for it is immaterial whether the limb is flexed on the body or the trunk is bent on the limb,—in either case motion in the joint results. This plan is adopted by Mr. Marsh, his patients being constantly confined to their beds. In the early stages of the affection this method of extension and counter-extension is correct so far as the beneficial local effect is concerned, but the protracted confinement as witnessed at the Alexandria hospital is objectionable, as tending to undermine the general health. This objection is largely overcome by confining the patient to a splint which, while allowing extension and counter-extension, enforces absolute immobility of the joint under all circumstances, and yet permits the removal of the patient from place to place, into the open air and sunlight, and even the riding in a child's carriage.

This splint consists of an iron frame covered with canvas, except a two- or three-inch space in the centre for convenience of defecation, two detach-able steel pieces, one upright at the foot, for extension from a stirrup-strap, and one a curved arm at about the middle stretching over and beyond the centre, for attachment of the counter-extending perineal straps. Webbing over the chest fixed to the sides prevents the patient from sitting up. Occasionally with a very restless child a third steel piece arches over the lower third of the thigh, to fix the knee. One inferior and both superior extremities are free, also the head and neck; otherwise there is immobilization of the trunk, with extension and fixation of the hip-joint.

On this "stretcher-splint" the nurse can carry the child from place to place and attend to all his wants. He improves in flesh, the pain rapidly disappears, and a happy countenance takes the place of the previous anxious look. No bed-sores form, though children have thus been confined from five to eight months continuously, and with the best results. Three to four months' use of the splint will usually suffice if the case is taken early and the constitutional cachexia is not too strongly marked. Following this a Thomas's splint should be used until the cure is complete. Complicating abscesses are to be opened promptly by incision, all antiseptic precautions being observed during the operation and in the after-treatment.

A rare cause of subacute inflammation of the synovial membrane is the presence of blood in the joint, found occasionally in cases of hæmophilia. To this I called attention as early as 1868, the joint involved in the case being the hip. It may attack any joint, the knee preferably. The symptoms are soreness of the joint, pain on motion, sudden swelling, possibly fluctuation, and slight heat. Immobilization and equable pressure cause absorption of the contained fluid and subsidence of the attack. The temptation would be great to tap the joint; but if there is any suspicion of the cause of the trouble, or if attention is called to the fact that the patient is a bleeder, all wounds should of course be avoided.

DISEASES OF THE MAJOR ARTICULATIONS.

By CHARLES T. POORE, M.D.

Disease of the joints is one of the most common surgical complaints of childhood: it is met with among all classes and in all conditions of life; no period is exempt from it. From the moment of birth (for a child may even be born with a diseased joint) to adult life articular inflammations are common. While these often yield readily to treatment when taken in time, they are, on the other hand, most rebellious and disastrous when neglected or treated improperly. The subject therefore demands careful consideration.

The structure of the articular ends of the long bones in infancy and childhood differs from that in adults in certain important respects; the younger the child the more marked is the difference. In early life the epiphyses are to a greater extent within the synovial cavity than in the adult; they are composed mainly of cartilage, with points of ossification in their centre; "they increase in all directions by interstitial growth, and the ossification advances from within outward;"[1] and they are separated from the diaphysis by the epiphysial cartilage or disk. Both the epiphyses and the diaphysial ends of the long bones are seats of exceedingly active formative processes. Not only do the epiphyses themselves increase in all directions, but the long bones grow in length by addition at their articular end. The parts in these situations are very vascular, and, as in all tissue where active growth is going on, healthy nutrition is easily supplanted by pathological processes. Recently-formed tissue has feeble resisting power, and therefore is less able to withstand morbid action. Another peculiarity that marks the difference between the infantile and the adult bone is that the nutrition of the epiphyses in childhood is not dependent on that of the diaphyses; this explains the fact that the diaphyses may be completely destroyed while the epiphyses continue to grow, and, on the other hand, the latter may be involved in disease while the former escape. These considerations render the study of joint-affections in childhood different from that of the same affections in adults. The nearer a child approaches puberty, the more does the course of articular inflammation resemble that in adults.

Joints vary in their liability to become affected with chronic disease.

---

[1] Macnamara, Diseases of the Bones and Joints.

The hip-joint is by far the most frequently involved; next the knee; then the ankle, then the shoulder, and last the elbow, of the larger articulations. The knee is most frequently attacked by acute affections, due probably to its size and its greater exposure to cold and injury.

Acute joint-affection is not so commonly met with as chronic, the latter being *the* surgical disease of infancy and childhood.

Diseases of the joints may be further divided into tubercular and non-tubercular affections; also into diseases beginning in the joint itself (synovial affections) and those commencing in the bone, the articulation being secondarily affected.

TUBERCULAR AFFECTION OF THE ARTICULAR ENDS OF BONES.

Tubercular affection of bones is a chronic disease; it is more frequently met with than any other, so that some surgeons almost deny the existence of a non-tubercular affection in children. Before considering the pathology of tubercular disease of joints, it will be necessary to define just what is meant by the expression "tubercular."

Formerly these chronic joint-troubles were called strumous or scrofulous. The expressions "struma" and "scrofula" were then applied to certain chronic inflammatory processes affecting the lymphatic glands, the skin, mucous membrane, testes, bones, and joints, and occurring almost exclusively in children and young adults, characterized by a tendency to spread by local infection, and prone to caseous degeneration.[1] A scrofulous individual, so called, was one liable to the occurrence of chronic inflammation of the tissues mentioned above, from the slightest exciting cause, the process being marked by rapid cell-proliferation, with defective power of organization. The term "tubercular" was limited to the gray granulations and caseous nodules affecting the lungs, viscera, and serous membranes. The scrofulous diathesis, it was admitted, was often inherited from tuberculous parents, and was accompanied by a tendency in the individual so affected to develop gray tubercles in the lungs or serous membranes; but a strumous person was not necessarily considered tuberculous in the then-accepted definition of the term. The strumous diathesis was looked upon as related to, but not identical with, the tubercular. Such were the commonly-accepted views held regarding the relation between struma and scrofula, and tuberculosis, although the line between them was getting exceedingly narrow; yet not until the last few years, when Koch proved that the two processes were pathologically identical, have they been obliterated. They are both manifestations of a chronic bacteritic disease, which is produced by a tangible organic contagion, and that contagion is a specific bacillus, and tubercle is an inflammatory product resulting from the presence of the bacillus in the tissue in which it has become lodged.[2] Inoculation of the so-called strumous material produces tubercle in the old acceptation of that term, and tubercular matter produces the so-called strumous deposit in glands; and, further, the tubercle-bacillus is found in both growths. All persons are not equally susceptible to tubercular infection: it therefore still remains to define that condition or state of the tissues which predisposes to, or affords a proper soil for, the lodgement and development of the bacillus. This is still called the strumous diathesis, meaning thereby a certain vulnerability or proclivity of the tissues to the development of tubercle. A better expression would be "tuberculous."

---

[1] Treves, Manual of Surgery, vol. i. p. 216.

[2] Marsh, Diseases of the Joints, p. 97.

It is a well-established fact that a child seldom inherits the bacillus; it simply is born with some defect in its constitution that predisposes it to the lodgement and development of tubercle in certain tissues.

This diathesis may by acquired in the course of any debilitating disease, from impure air, bad food, or unhealthy surroundings. The exanthematous diseases may and often do implant upon the tissues of a previously perfectly healthy child a soil in which the bacillus can gain lodgement and thrive.

The bacillus gains access to the body either by the respiratory passage, by the intestinal tract, or through a wound. Whether it will obtain a lodgement and develop depends upon the resisting power of the tissue: if the child is healthy the bacillus will be arrested in its development and kept at bay until it is finally eliminated or destroyed; if, on the other hand, his vital powers have not sufficient resisting force, it gains lodgement and grows under certain unknown conditions.

It is generally considered that joints are infected from some other foci in the body. Baker[1] states, "It is almost certain that in tubercular disease of joints we are dealing with a secondary infection in the vast majority of cases; that the organism introduced into the system elsewhere and present in the blood has found in its wanderings a home peculiarly fitted for its growth in the tissues of the joint. There are only two tissues about a joint in which the bacillus can find lodgement,—the synovial membrane and the cancellous tissue of the bones."

Some months ago I operated upon a robust, well-nourished child five years of age for tubercular disease of the wrist-joint: there was nothing of interest about the operation. The child died in a few weeks from diphtheria; and on post-mortem examination tubercles were found in the lungs and the bronchial glands were filled with caseous matters of much older date, some of them showing calcareous degeneration. No tubercles were found about the seat of operation. The bones of the wrist were in all probability infected from the glands.

There are two circumstances which contribute to the development of tubercle in the articular ends of bones in children: first, the active nutritive process going on at the articular ends of growing bones, which means greater flow of blood to the parts; and, secondly, the low vitality of the new tissue; for it is a well-known fact that the cells of recently-formed tissue have weak resisting power,—in other words, their vitality is low. In a child who has either inherited or acquired a "tubercular diathesis," whose tissues have therefore less resisting power than a healthy child's, the bacillus circulating in the blood from an old deposit would gain lodgement in those parts of the body less able to resist it and those to which the supply of blood was less free. There is no tissue in the body in which these conditions are more perfectly filled than in the articular ends of growing bones, and practically we find them the most common seat of tubercular disease. A perfectly healthy child, one in whom there is no tubercular predisposition either inherited or acquired, will not develop strumous disease of a joint, any more than a perfectly healthy adult under similar circumstances will develop tuberculosis of the lungs; but if the adult be exposed to vitiated air, privations, or bad hygiene, he may and often does engraft upon his constitution a condition congenial for the development of tubercle; and the same holds true in regard to joint-disease in childhood. Baker states (*loc. cit.*), that "there are several kinds of predispositions to tubercular disease of joints. In the first place, a peculiar debility may be inherited from a phthisical or otherwise unhealthy parent, rendering the tissues of the child generally less capable of repelling the attack of the parasite than had it come from a robust stock; next there is the general predisposition of early age, the tissues of the young having less resisting force than those of the mature. Thereby certain locations of the body appear to be particularly open to the attacks of the organism, probably owing to the hurried physiological changes involved in rapid growth in them,—changes which are associated with the presence of abundance of almost embryonic tissues and great vascularity."

---

[1] British Medical Journal, 1888, vol. i. p. 1259.

There may be and often is another contributing cause of bone-tuberculosis called an "exciting" cause, and that is injury. Traumatism renders the tissues more open to the deposit of the bacillus present in the blood, in several ways. It may cause more or less inflammation with exudation; such exudation is of lower vitality than the normal structure, and therefore of less resisting power, and thus forms a favorable nidus for the lodgement and growth of the bacillus; and the increased flow of blood to the part brings a greater supply of the parasite. Injury may cause a loss or lowering of the vitality or tone of the tissues, favoring passive congestion; this slowing of the current offers a better chance for the deposit of the contagium. Contusions of the bones may cause more or less extravasation of blood, and with the blood the bacillus also escapes, and in this situation meets with the most favorable conditions for further growth. Baker (*loc. cit.*) considers the last-mentioned effect of injury the most potent factor in determining the point at which tubercular disease makes its appearance in those who, by inheritance or physical conditions, have acquired a soil congenial for the development of the parasite. Tubercles, having become deposited in the cancellous tissues at the end of a bone, act as an irritant, and, as a rule, inflammatory processes take place about it, so that fibrin is thrown out, forming a capsule around it. The contents of the capsule after attaining a certain stage of development undergo retrogressive changes, owing to the lack of blood-supply. These are of a caseous, fatty, and necrotic character. Sometimes this limiting tissue consists of sclerosed bone; after a time, in certain cases, the contents of the shell undergo liquefaction, which may finally break through its limiting membrane and further infect the bone, forming new and larger deposits filled with bony detritus and charged tubercular matter. If these bone-abscesses are of any size, they often contain sequestra.

Savory[1] has drawn attention "to the analogy that exists between the progress and effects of tubercle in the lungs and in the bone. The cancellous texture of bone, which is the seat of tubercle, resembles broadly in physical characters the parenchyma of the lungs. . . . In both cases the spongy texture appears to be filled up and rendered solid by the infiltration of caseous deposit; then, too, the resemblance further appears in the halo of inflammation or increased vascularity of varying width which so often surrounds the mass. Still further is the likeness shown in the mode in which tubercle degenerates. The included tissue is broken down and destroyed, until a cavity is left in the cancellous bone corresponding remarkably to a vomica in lung. Further, the likeness is extended by the relation of cancellous bone to the neighboring joint and the relation of the lung-substance to the pleura."

König divides bone-tuberculosis into three classes: (1) the dry form, where there is a tendency in the tubercular mass to be transformed into cicatricial tissue and thus prevent the distribution of the bacillus; (2) those cases in which the vegetation degenerates into a soft gummous detritus, which shows a disposition to infect the tissues in its immediate vicinity, and thus tends to the spread of the disease; (3) an infiltrating variety, in which the bone becomes infiltrated with tubercle, showing no limiting barrier; the cancellous tissue of the bone becomes rapidly involved in one mass of disease. In the latter form the joint soon becomes infected, and the patient dies early from general tuberculosis. As long as the walls of these tubercular foci remain unbroken, or do not become infected, extension of the disease does not take place. The tendency of these deposits to undergo changes is great: it is always either towards cicatrization or towards liquefaction and caseation. The size of these caseous deposits varies: they may occupy a considerable space of the end of the bone, or may be confined to a small area.

Tubercle in bone in its early stage is invisible to the naked eye; later, however, after it has acted as an irritant and increased in size, a halo of inflammation or vascular redness appears around the deposit; sometimes a caseous mass of considerable size is surrounded by this vascular zone, which gradually shades off into the healthy bone. In some examples, if these deposits are not of recent formation, the mass will be surrounded with a shell of sclerosed bone, due to the osteitis that has taken place around it. When first visible, a solitary tubercle appears as a semi-transparent circular spot, with an opaque centre, quite bloodless, and often with a somewhat irregular border, the surrounding bone-medulla being of a deep-red color. The junction of several isolated tubercles forms a mass of granulation having a grayish, granular, semi-transparent aspect, or, if the disease is of long standing, the patch presents a decidedly caseous appearance. At the periphery of such masses the medulla is observed to contain no fat-cells; its blood-vessels are dilated, and no longer have connective tissue around them.[1] When tubercular granulations develop in bone, they produce obliteration of the existing blood-vessels, and this leads to caseous degeneration. These slowly-progressing caseous patches are often preceded by a chronic osteitis, and terminate in suppuration, with softening and destruction of the proper bone tissues, and finally in perforation of the bone. In other examples—those in which the bone has become infiltrated with tubercle—there is no limiting inflammatory exudation: the whole bony tissue is softened and filled with the products of inflammation,—namely, pus, broken-down osseous tissue, and tubercular matter; the bone is spongy and dark-colored and can easily be crushed under the fingers. If the tubercle takes on a cicatrizing process, the parasite is in time destroyed, and the remains of the deposit are represented by a mass of fibrous tissue. In excising joints we often meet with irregular-shaped spaces in the bone filled with firm connective tissue: these are the remains of tubercular deposits which have undergone the cicatrizing process. In cases where the deposit, although at first confined within narrow limits, has liquefied and either broken through or infected the limiting zone of inflammatory exudation, the bone may become infected, and general tubercular infiltration of the cancellous tissue may follow, as in the first-mentioned variety. Often the deposit breaks down and forms a cavity in the bone of greater or less size; this may either become a caseous mass or discharge in the direction of the least resistance, and this, too, is often into the joint-cavity. In its slow progress towards the joint the bone is destroyed and the cavity becomes enlarged, containing broken-down tubercular matter, bony detritus, and frequently sequestra of varying size; finally the articular lamella of bone is reached and the joint involved. Sometimes these tubercular abscesses have a different history; they make their way to the surface of the bone entirely outside of the joint-cavity, perforate the compact tissue, form collections of matter in the surrounding soft parts, and finally open through the skin; we then have a sinus leading to a cavity in the articular end of the bone, often containing a sequestrum. Even when they follow this course the joint, in many cases, does not escape, for the disease may also travel towards the articulation and involve it. The ultimate result, so far as the joint is concerned, depends upon the situation of these tubercular deposits and the course pursued by them, whether they take on a cicatrizing process, break down and discharge into the joint, or infiltrate the cancellous tissue in the end of the bones. If the tubercular deposit takes on a cicatrizing process and is replaced by connective tissue, the parts around return to their normal condition and give no further trouble. In cases where the tubercle breaks down, liquefies, and caseates, and becomes surrounded with a shell of sclerosed bone, it may cease to act as an irritant to the parts and may remain an indefinite time without giving any trouble, all pain having ceased and the child going about without any discomfort; or there may be pain about the bone at times in damp weather or after exercise, sometimes tenderness over the parts on pressure, often aching of the limb, passing off and reappearing again. I have seen quite a number of cases giving such a history, and have always found, when any operation has been called for, that there were caseous masses of considerable size in the end of the bone, the joint-trouble having ceased, or showing only the remains of previous disease. Finally, in those cases in which an abscess is formed in the bone it may progress until it opens into the articulation.

[1] Cornil and Ranvier.

The joint may be affected with disease in two ways: first, by contiguity of tissue; secondly, by the opening of a tubercular abscess into the joint-cavity. It should be noted, however, that the articulation is frequently first affected in the former way, while later it is infected directly from the abscess.

As these bone-abscesses increase in size, more and more of the cancellous tissue becomes involved, and the area of the inflammatory halo extends until it approaches that portion of the bone to which the articular cartilage is attached and from which it gains its nutrition; finally it reaches a point just within this tissue. The effect is first to cause congestion, and later to diminish and then cut off the vascular supply. The articular cartilage first loses its bluish color and becomes of a yellowish hue; later it is raised like a blister from the bone over an extent of surface corresponding to the extent of the disease in the bone behind it; finally a perforation takes place, and the contents of the abscess gain access to the articulation. These holes in the cartilage have a very characteristic appearance: they have clean-cut edges, as though they were cut out with a punch; their contour is often irregular; the surrounding cartilage retains its normal white color. Often there are a number of places presenting this characteristic loss of substance, depending upon the amount and extent of the disease in the bone; at times the whole bone under the cartilage will be affected with osteitis, and will present an irregular granular appearance and be covered with exudation. In such cases the whole articular cartilage may be detached in a mass, like a cap, from its bony attachment. In other cases only islets of apparently normal cartilage will be seen, the rest of this tissue having been destroyed. In all these cases the joint has long been disorganized, its capsule is perforated, and abscesses have appeared in the soft parts. Before these changes have taken place, and previous to the perforation of the cartilage, the joint often becomes distended with fluid, due to the extension of the inflammation by contiguity of tissue. These attacks of synovitis are often of short duration at first, coming on after some injury or too much exercise; after a few days' rest they pass off, only to be repeated, however, on the repetition of the exciting cause. Soon the joint-swelling will come on upon less provocation, and the distention will be slower in disappearing, until finally the effusion will persist and the joint continue enlarged. In these cases the contents of the joint may slowly become purulent, so that when the tubercular abscess opens into the joint no further increase of the symptoms takes place. Tubercular deposit may take place in the synovial membrane as well as in the bone, and the two processes go on together.

Necrosed pieces of bone of varying size are frequently met with in connection with bone-tuberculosis; they often preserve some point of attachment to the bone; they are frequently of a wedge shape, with the base directed to the neighboring joint, while the apex looks towards the medullary cavity. Between the sequestrum and the healthy bone immediately surrounding it there is a layer of firm tubercular granulation which joins it to the bone, the latter being frequently diseased.[1]

A good result has been obtained in all varieties of tubercular disease of the ends of the bones except the infiltrating variety. It is produced only after the destruction of the part involved, by the discharge of the abscess through a sinus, if the deposit has marked necrotic changes, and later by the formation of cicatricial tissue. The firmer the granulation and the fewer the tubercles, the more likely is it to become replaced by firm fibrous tissue; the greater the softening, the more liability is there to suppuration and the more protracted is the course of the disease.

TUBERCULOSIS OF THE SYNOVIAL MEMBRANE.

Tuberculosis of the synovial membrane is a frequent disease in childhood. Formerly it went under the names of pulpy degeneration, white swelling, and tumor albus; more recent pathological research has demonstrated that it is a tubercular disease of the synovial membrane.

The earliest manifestation pathologically of tubercular disease of the synovial membrane consists in a swollen, opalescent condition of the membrane; it is filled with inflammatory products. The surface soon loses its smooth appearance, and by degrees assumes the aspect of granulation-tissue. As the disease progresses, the membrane becomes thickened, soft, and friable, and here and there, both in the membrane itself and in the subsynovial tissues, masses of caseous material are formed.[2]

When once established, the inflammatory process extends until the ligaments, cartilage, and often the ends of the bones, are involved. As the disease of the synovial membrane advances, this semi-solid gelatinous tubercular material gradually extends, and slowly permeates all structures of the joint and fills its cavity. As soon as the cartilage is overlapped by this pulpy material, it loses its natural bluish-white tint and polished surface and becomes of a yellowish, dull, and opaque color. It soon undergoes erosion, slight at first, but these spots soon deepen until the underlying bone is reached or the synovial membrane acquires adhesions to its surface; vessels enter its substance, and a number of pits and excavations are formed containing granulation-tissues; these increase and unite, so that by degrees the bones become denuded and more or less diseased. This gelatinous material permeates and infiltrates all structures, and may extend to the tissues outside of the joint. Through this newly-formed tissue blood-vessels penetrate. In many cases abscesses form in this thickened tissue from caseous deposits, and open either within the joint or external to it. On opening such a joint when the disease is advanced, the whole cavity is found filled with this semi-transparent gelatinous material, the ligaments are swollen and softened, the cartilage is more or less destroyed, and the bones are diseased: in fact, every tissue of the articulation has been invaded by this pulpy material. Through this mass are frequently found collections of thin, unhealthy-looking pus. Outside of the joint the parts are also often infiltrated, of a pale, unhealthy color, and considerably swollen.

[1] Jones, Diseases of the Bones, p. 179.

[2] Marsh, Diseases of the Joints, p. 99.

It is a slow, insidious disease, often ending in a general arthritis and in total destruction of the articulation, and even in death. Its exciting cause may be an injury, or it may come on without any apparent cause. It never makes its appearance except in those of a tubercular diathesis.

The general treatment of a child affected with joint-disease calls for but brief notice. The necessity for keeping the patient in as good a condition as possible is so well recognized that any remarks on the subject are needless. Tonics, fresh air, pleasant surroundings, and nutritious food are of incalculable benefit, and without them our best efforts at local treatment will be disappointing. We can give no medicine which will have any direct effect on the joint-affection: we can only influence it by attention to the health of the patient. It may be laid down as a rule that in children who are of low vital powers and whose general condition is depressed, joint-disease will progress no matter how rigidly the local treatment may be carried out; while, on the other hand, any improvement in the general health of the child will place him in a better condition to overcome the joint-disease. Suppuration is present in many cases; and a general consideration of the management of abscess is presented in another place.

The general symptoms of tubercular osteitis are limited motion, lameness, swelling, and deformity. These usually come on in the order named. In all cases of tubercular osteitis the joint, if affected, is involved secondarily; in certain cases it may escape infection. In the early stage of the affection we have to deal with only a bone-lesion, and the treatment of this condition is the same as that of similar disease more distant from the joint. After the articulation has become involved another element is added, although the local management of the joint-trouble is the same as that of the bone-lesion. Disease beginning in the synovial membrane calls for the same management as disease beginning in the bone. Thus the treatment of joint-diseases may be considered collectively, and our main dependence must be placed upon affording to the affected articulation absolute rest. But consideration of the general treatment of joint-affection would be very incomplete without a clear understanding of the mechanism and therapeutic use of extension in the management of acute and chronic joint-diseases.

Spasm is one of the most constant and painful symptoms of inflammation of the larger joints, especially when the bones are involved: it is the cause of the painful startings so common during the course of the disease; it disturbs the rest of the patient, and is no small factor in keeping up and aggravating the local trouble. Although it is universally admitted that rest is an absolute necessity, yet, from the want of a clear understanding of what is meant by rest, the method of obtaining it is often very imperfectly carried out.

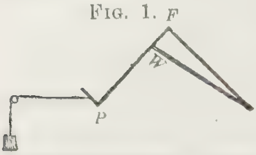
Mr. Marsh, in a chapter "On the prejudicial effects of intra-articular pressure, and on the danger of producing it by surgical appliances," in his work on "Diseases of the Joints," has so clearly spoken upon this subject that I cannot do better than make very free use of this chapter. He says, "All will accept the general proposition that rest is essential in treatment of inflammatory disease of the joints; yet there are some points which require to be insisted upon in order that the principle may be adequately carried out. There is present in all cases reflex contraction of the surrounding muscles. In the majority, however, it is only slight, and sufficient merely to secure more or less fixation and protection of the affected joint. Neither in the shoulder, wrist, elbow, nor ankle does it become excessive, so as to lead to either deformity or excessive pain. All the joints when first attacked are placed in their respective positions of greatest ease, and their positions are maintained undisturbed by muscular spasm through even long periods of active disease. In disease of the shoulder the arm remains at the side; the elbow is kept at an angle of about one hundred and twenty degrees; the wrist is slightly dropped; the ankle is fixed in a position of slight equinus. Both the hip and knee, however, offer a strong contrast to all these instances. They are liable to the influence of constant, and often violent, spasm in the surrounding muscles, which frequently leads to severe suffering and to irremediable deformity. To secure rest to a diseased joint, all its component structures must be taken into account, and the different sources of disturbances must be kept in view. The synovial membrane must not only be defended from mechanical disturbances by movements of the joint, which have the effect of dragging upon and compressing its swollen processes and fringes; it must also be relieved, as far as possible, of its function of secreting synovia; while if it becomes distended by effusion, appropriate means must be taken to remove this condition. The articular ends of the bone must be in the same way relieved of their ordinary functions of sustaining the pressure to which they are exposed, not only when they are engaged in transmitting the weight of the body, but also during muscular action. . . . The tibia, in cases of the knee, for example, is a lever acted on by the surrounding muscles, and having the condyles of the thigh-bone as its fulcrum, and whenever the muscles contract so as to move the tibia its upper end is pressed against the femur. Hence to place the knee-joint at rest is necessary not only to protect the synovial membrane from disturbance, and to relieve it from the active discharge of its secreting functions and to prevent the patient from bearing weight on the limb, but also to remove the intra-articular pressure resulting from muscular contractions. . . .

"The conditions, however, under which a diseased joint is placed are widely different. Pressure depending upon superincumbent weight may, it is true, be removed by position, but, in consequence of reflex irritation, the muscles are kept in a state of contraction, which in the hip and knee is often so spasmodic and so violent that it is attended with extremely painful jumpings and startings of the whole limb. The force with which the muscles act exceeds normal contraction as pain exceeds natural sensation. . . . Its amount is indicated by the suffering it causes, when, as is often the case, the slightest movement of the limb or a light step across the floor or even in an adjoining room brings on a condition of spasm which makes the patient cry out with pain. . . . Under these circumstances the articular ends of the bone are not only deprived of the usual respite from pressure which constitutes their physiological rest, but, diseased as they are, and therefore so much the more in need of rest, they are exposed hour after hour, or even week after week, to an amount of pressure which is often in many cases in excess of that to which they would be exposed, except on very rare occasions, in the condition of health.

"Any scheme for treating the hip or knee, therefore, must include a provision for the relief of intra-articular pressure. There are at present two principal methods by which this may be attempted. (1) The joint may be placed in some form of rigid apparatus which prevents movement, and under the influence of which muscular spasms will subside. In all joints except the hip and knee, and in many instances in these also, this method is efficient and leaves nothing to be desired. . . . (2) Weight-extension may be employed. . . .

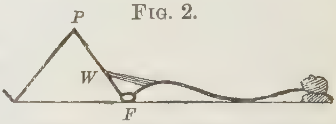
"Yet there lies at the bottom of the successful application of weight-extension a principle which is frequently overlooked, and the result is that, instead of acting so as to relieve intra-articular pressure by drawing the surface out of abnormally close contact, extension has exactly the opposite effect, for it brings the articular ends still more firmly together. (Fig. 1.) If the weight is attached to a limb that is in the position of extension, its tendency is to draw the joint-surfaces apart. In the majority of cases, however, in which the weight is used, the joint is fixed in a position of flexion, and does not admit of extension. Now, if the weight is applied in the usual manner when the limb is flexed, it will be seen by looking at Fig. 1 that the force called into play is really that of leverage of the second order. The traction-weight to the foot is the power acting on the lever formed by the tibia; the resistance to be overcome is in the contraction of the ham-string muscles (inserted just below the head of the bone) and the ligament structures at the back of the joint; the fulcrum is constituted by the condyles of the femur. The effect of the traction-weight is, therefore, to bring the head of the tibia into firmer contact with the condyles of the femur. In the same way in the case of the hip-joint (Fig. 2) the weight attached to the foot acts on the femur as the power tending to overcome the resistance offered to extension of the thigh on the trunk by the rigid psoas and iliacus inserted into the trochanter. If the parts are examined when the weight has been applied, it will be found that the limb has come down into a horizontal position while the pelvis has been rotated so as to produce curvature of the lumbar spine forward, as in Fig. 3. This change in the position of the limb, however, does not alter the force that is being employed. The force is a leverage still, and the intra-articular pressure is still in action. In order to prevent this effect of the weight, it is necessary to proceed in the following way.

FIG. 1.



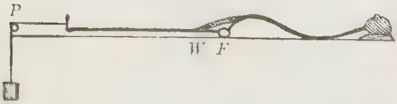
WEIGHT-EXTENSION ACTING AS LEVERAGE IN CASE OF THE KNEE. *P*, pulley; *W*, weight; *F*, fulcrum. (Marsh.)

FIG. 2.



POSITION OF THE LIMB IN HIP-DISEASE IN WHICH WEIGHT-EXTENSION ACTS AS A LEVERAGE.—*P*, pulley; *W*, weight; *F*, fulcrum. (Marsh.)

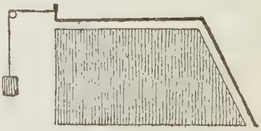
FIG. 3.



WEIGHT-EXTENSION ACTING AS A LEVERAGE IN HIP-DISEASE.—*P*, pulley; *W*, weight; *F*, fulcrum. (Marsh.)

"In case of the knee, the thigh being fixed, the extension must be made in the long axis of the leg. This is most conveniently done by placing the limb on such a framework as is shown in Fig. 4. The plane for the thigh should form an angle of about sixty degrees with the surface of the bed. If it is more oblique, the leg will, if there is any flexion, approach the perpendicular, a position not only inconvenient, but likely to induce œdema of the foot. . . .

FIG. 4.



POSITION OF THE LIMB DURING EXTENSION FOR DISEASE OF THE KNEE. (Marsh.)

"On the same principle, when the hip is the affected joint, the leg being extended on the thigh, the limb must be raised until the spine is free from anterior curvature, and must then be supported in this position. The weight being made to act in the long axis of the limb, as the deformity is reduced the apparatus must be rearranged by reducing the height to which the limb is raised."

Extension applied to the hip or knee as in Figs. 1 and 2 often increases the amount of pain and spasm: in such cases the weight is often increased, upon the supposition that it is not heavy enough to overcome the spasm of the muscles, with the result that the pain and muscular contractions are augmented rather than relieved. The cause of this is evident: the intra-articular pressure has been increased, and with it the disease.

When a joint is straightened under ether, if the muscles are shortened it is only by stretching them that the deformity can be overcome, and here again we use the inflamed bone as a fulcrum, the leg or the thigh as a lever, and the shortened muscles as the weight, and nothing but injury to the bones can be expected. When such a course of treatment is adopted, it is always followed by increased heat, pain, and swelling, and it is often some time before the joint recovers.

A posterior splint with a joint opposite the articulation and worked with a screw acts upon the same principle: the articular ends of the bone, being the fulcrum, are crowded together, and injury is caused to the inflamed joint. Such applications if they fasten firmly enough to act cause so much pain and discomfort that they have to be removed, while if they are applied loosely they are useless to accomplish any good.

Another subject which may conveniently be considered in this connection is surgical manipulation of joints that have been the seat of disease or injury. It may be laid down as a rule that whenever a joint has been seriously diseased, and especially when it has been the seat of a tubercular affection, manipulation, with the view either to correct an abnormal position or to gain motion, is a procedure full of danger to the articulation and often to life. No amount of force can restore the structures to a condition in which they can resume their functions if the cartilage has been destroyed; if it has not, the danger of setting up anew the inflammation is great. Those who have attempted to break up adhesions in a joint of this character have always done injury; and even if there has been a temporary improvement the limb soon returns to its old vicious position, and nothing has been gained.

It should be a rule never to interfere with an articulation that has been the seat of tubercular inflammation. There are, however, certain conditions in which forcible manipulations are not only admissible but are even called for in order to restore motion to a crippled joint. These are cases where the joint has been the seat of acute synovial disease and where adhesions have been found limiting the amount of motion,—cases in which adhesions have formed outside of the capsule, after a sprain or an extra-articular abscess. In such cases there is often pain upon motion, but the articulation is cold and the parts are often swollen. In many of these cases the joint is healthy, and the limitation of motion is due to fibrous bands outside of the joint.

An opinion as to the advisability of resorting to forcible manipulation is formed from a history of the case and the condition of the part. If there is evidence that the limitation of motion is not due to tubercular trouble, if there is a history of some traumatism,—a sprain or blow upon the joint,—if there has been only a periarticular abscess, the probabilities are that the joint is healthy, and that the lameness is due to bands of adhesion either within or without the articulation. Joints that are suitable for manipulation are free from abnormal heat, or if any heat is present it follows exercise and rapidly subsides after rest. In many cases they are abnormally cold, and the skin is dark and mottled. There is often pain upon motion, and the parts are œdematous and swollen. It is often impossible to state just what is the condition of the parts, yet these are the cases which are cured by forcibly bending the joint. The operation is performed under an anæsthetic; gas may be used, but all muscular resistance must be abolished, so that the force is brought to bear upon the adhesions and their rupture can be easily appreciated. The joint should then be thoroughly flexed and extended. During this procedure the bands are often felt and even heard to give way. There is no after-pain. The patient soon regains painless use of the limb.

ABSCESS.

There is a great difference of opinion in regard to the proper management of abscess in connection with joint-disease, between those who confine themselves to the mechanical treatment of diseases of the articulation and the general surgeon. Many of the former allow abscesses to increase and burrow among the soft parts until they make an opening for themselves; the latter holds that they should be evacuated as soon as they are discovered, thoroughly drained, and treated like similar collections of matter in other locations.

Abscesses may be either intracapsular or extracapsular, or, as is more generally the case, they start within the articular cavity, in time perforate the capsule, and then burrow in the soft parts; they may in a few cases be extra-articular at first, but, as a rule, they soon communicate with the joint-cavity. The only exception to this is where there exists an abscess in the end of one or both of the bones forming the articulation, which has opened external to the capsule, and where the joint itself is affected only by contiguity of tissue and not by infection from the bone-abscess itself. But in whatever way these collections of pus may have formed, or wherever situated, only one course of treatment must be followed. It may be laid down as a rule that as soon as pus is formed in a joint it should be treated like an abscess in any other locality, and that its presence within the capsule does not in any way form an exception to the inflexible rule that it should be at once evacuated. An articular cavity containing pus is no longer to be looked upon as a serous sac: its functions as a joint have been destroyed, and it has been reduced to a cavity containing pus,—nothing more nor less; the simple fact being that we have a sac bounded by a dense inelastic wall, secreting purulent matter, which, sooner or later, will perforate its fibrous surroundings, form a new abscess among the soft parts, and finally open through the skin and discharge, after burrowing, it may be, for a considerable distance. There is no difference between an extracapsular and an intracapsular abscess, except that the latter is more serious and more dangerous to the life and integrity of the articulation; and therefore, if pus in the soft parts demands active treatment, the same rule must hold good, with even greater force, in regard to collections of matter connected with joint-disease, whether they are acute, subacute, or chronic.

Mr. Marsh divides abscesses in connection with joint-disease into three classes. (1) The acute,—those which form in acute suppurative synovitis, in general arthritis, and in pyæmia. They are attended with high temperature and marked constitutional symptoms; they are sudden in their advent, and, if allowed to run an unrelieved course, destructive not only to the integrity of the joint involved, but often also to life itself. Acute abscess may form in the course of any chronic joint-trouble, either from injury or from the bursting of an abscess of the bone into the articulation. (2) Those that form later in the disease, and generally are connected with tubercular or non-tubercular disease of the bone. They are often slow in their formation, frequently unattended with any marked symptoms, with no great elevation of temperature, and with but little pain, especially those forming about the hip-joint. Yet, if careful investigation is made, a history of increased pain and exacerbation of the joint-disease may be made out. In the more superficial joints increased swelling and pain are often complained of. In other cases an evening elevation of temperature may be noted for some time, with more discomfort in going about, or even pain at night, and with swelling of the surrounding soft parts, often followed by a sudden diminution of the more acute symptoms as soon as the pus has perforated the capsule and diffused itself in the surrounding tissues. (3) Residual abscesses,—those which develop when all disease has subsided, and which involve the old inflammatory products, as the remains of an old abscess that has undergone caseous degeneration, etc. These may not make their appearance until months or even years after the disease of which they are the result has passed. They are often acute in their advent, attain considerable size if the pus is allowed to accumulate, and are attended with marked constitutional symptoms. These abscesses may also have their origin in the inflammatory products infiltrated in the soft parts, which have low vitality, and on the receipt of an injury, from failure of health or some unknown cause, break down, and an abscess of greater or less size results.

The course of an abscess in connection with joint-disease varies. When collections of pus are allowed to follow what is called their natural course, if they are intracapsular in the beginning a time will arrive when they will perforate the capsule and burrow in the soft parts, following often the muscular planes, and frequently extending far from the joint before they approach the surface and discharge. These cold abscesses sometimes contain a pint of pus; the soft parts are undermined; the muscles are dissected from one another and their nutrition is greatly impaired. The walls of such an abscess-cavity are thick, and lined with exudative material filled with spores, which tend to keep up the suppuration. When these abscesses have their origin in tubercular disease, they always contain the tubercle-bacillus, and the danger of infection of other parts of the body is great. When recovery takes place after one of these abscesses has run its course, the muscles are bound down by adhesions,—it may be to the bone or to one another,—the limb is covered with scars, and its ultimate usefulness restricted. In some cases the abscess does not travel far before it makes an opening for itself and discharges. In superficial joints, as a rule, it soon perforates the skin, and continues to discharge through a small sinus for a long time. An abscess often takes on a more acute course. As the opening is small, either from granulations or from some other cause, it does not afford adequate drainage: the pus therefore accumulates, and the soft parts become inflamed and swollen, until either a new opening is formed or the old one is dilated. In this way the limb becomes riddled with sinuses and the skin undermined. One would be greatly criticised for not opening an abscess in the soft parts: why should he not be equally condemned for not giving exit to pus when it happens to be in or about a diseased joint? We often hear it claimed that because the collection of pus sometimes, if left alone, dries up and never gives further trouble, therefore all abscesses should be allowed to pursue their natural course. It is true that these abscesses sometimes caseate, but it is the exception and not the rule; and even when they do, their remains are always a source of danger, from the liability to the formation of residual abscesses.

The advocates of the let-alone management of collections of matter in connection with joint-disease look upon the presence of an abscess "as at least an evil attended with compensating advantages; their occurrence appears to shorten the duration of the affection. . . . There is no evidence that the discharge, as such, exhausts the strength of the patient."[1]

It is true that in some cases these abscesses disappear and the caseous deposit does not give any further trouble, but it is *not* the rule. It is within the experience of every one who has seen much of joint-diseases, to have had much trouble from these remains of old abscesses; and the fact should not be forgotten that these caseous deposits are able to infect the system,—that is, if they are similar to caseous deposits in connection with tubercular disease elsewhere. Again, amyloid degeneration holds a close relation to suppuration; at least we do not find this secondary change in the viscera except in cases that have gone on to suppuration. It is not intended to deny that abscesses in some patients do well,—that is, that a good recovery takes place; but the question is, is the let-alone plan a safe one to follow as a rule of practice, and is the constant discharge of pus through sinuses often long and numerous, the frequent formation of new abscesses, or the filling up of old ones, an advantage to the patient?

Suppuration, whether it is profuse or only slight, always tends to undermine the patient's health, and the larger the abscess the greater will be the suppuration after it has formed an opening for itself. The more one can limit the amount of pus, the less will be the danger of hectic and amyloid degeneration, and the better will be the chance of recovery from the joint-disease. The fear of free incisions is due to the disastrous results which followed such procedures before the present method of wound-management was adopted, and statistics quoted to prove the danger of interfering with these collections of pus are misleading and prove nothing.

---

[1] Judson, New York Medical Journal, 1885, vol. xli. p. 116.

What, then, should be the treatment of abscesses in connection with joint-disease? *Whether they are intracapsular or extracapsular, they should be opened as soon as they are discovered, thoroughly drained, and treated according to the well-established rules of antiseptic surgery.* Marsh[1] makes the following statement in regard to abscesses: "That matter should be evacuated as soon as it is detected must be strongly advocated in all instances of suppuration resulting from scrofulous disease."

The following is the method usually adopted in opening these abscesses. The parts around the abscess should be thoroughly washed and rendered aseptic by covering them with a towel wet with mercuric solution (one in one thousand) some time before the operation. An incision is made of ample size down to the abscess-cavity in such a position as to insure the best drainage; the cavity is then entered, well evacuated, and washed out at once; its walls are next thoroughly scraped with a Volkmann's spoon, so as to remove all the lining membrane of the sac; it should again be thoroughly flushed out with the antiseptic solution. If the abscess connects with the joint, that should also be cleaned out; any carious bone may be gouged and then washed out. If there are any sinuses, they should be well scraped, or, better, dissected out, so that no diseased tissue is left, and the abscess- and sinus-walls may unite and obliterate the old cavity. The drainage should be so arranged, if possible, that any discharge will not pass through the old cavity, and if the joint has been entered the drainage should be from the most dependent parts of that cavity, independent of the location of the abscess. The part may then be dusted with iodoform, drainage-tubes inserted, and the wound closed with catgut ligature. A strip of iodoform gauze should be laid over the line of the incision, and over this an ample dressing of antiseptic gauze, and the limb thoroughly immobilized.

Under this treatment it will be found that the temperature, if it has been elevated, will fall, the pain cease, and if the abscess is an acute one it may never give any further trouble. In case, however, it is connected with diseased bone, a sinus will remain; but we have gained this: that the pus from the joint will as fast as formed drain away by the shortest route, and if the drainage-tube is properly placed there should be no further accumulation of pus; this reduces the danger of the matter burrowing to a minimum, and the patient is saved the pain and discomfort of the formation of new abscesses. The dressings should be renewed as often as they become soiled.

---

[1] Diseases of the Joints, p. 115.

The after-history of these abscesses varies according to their causes. In some cases, if the abscess is acute and not connected with diseased bone, we may hope by proper treatment to evacuate the pus so that it will not again collect. In other cases, no matter what course is pursued, we must look for new accumulation until the disease of which it is the result has subsided. The latter are cases of chronic abscess, and are almost always connected with tubercular disease of bone, in which pus will continue to be formed—it may be only in small quantities—as long as the bone-disease lasts; or the abscess may be connected with necrotic or carious bone of a non-tubercular nature. The gain in treating these chronic abscesses is that we provide drainage to the joint by the most direct route, so that the pus does not collect, and therefore the patient escapes the disadvantage of large purulent collections, long sinuses, and increased suppurations.

Tubercular abscesses may be treated by emptying them through a thoroughly disinfected trocar and then injecting the cavity with a solution of iodoform and ether (five parts of iodoform to one hundred parts of ether). Abscesses treated in this way, if the bone-disease has terminated, may never refill. After evacuating the abscess an ounce or two of the solution is injected into the cavity, and then, gently kneading the parts in order to distribute it evenly, the rest is allowed to run out through the canula.

Poultices should never be applied to discharging abscesses; if these are acute or inflamed and the parts red and swollen, their condition is due to retention of pus from inadequate drainage, and a free incision will afford prompt relief. The use of poultices encourages suppuration, and is not permissible in antiseptic surgery.

DISEASE OF THE HIP-JOINT.

Hip-joint disease in the natural sense of the term means no special complaint, but for years has been applied to a chronic tubercular affection of that articulation, very commonly met with in children. It has been called chronic articular arthritis, morbus coxarius, tubercular disease of the hip, coxalgia, etc.; but by whatever term it is designated it consists of a tubercular inflammation of the hip-joint.

It is met with among all classes during childhood. It may begin either in the bones or in the synovial membrane, is slow in its progress, and tends to the total destruction of the articulation. Its frequent occurrence, its insidious beginning, its disastrous tendency, and the varying views held by different practitioners as to its cause and management, contribute to make its study one of the most interesting and important of any articulation.

The disease, according to Gibney, is as frequent in girls as in boys: thus, out of four thousand one hundred and twenty-five cases of the affection occurring in children under six years of age, two thousand and thirty-eight occurred in girls and two thousand and eighty-seven in boys. The trouble usually begins before the sixth year, although it is not uncommon in older children.

As stated above, hip-joint disease is a tubercular affection. It is never developed in healthy children, but always in those who, through inheritance or ill health, possess a certain vulnerability of their tissues, which hence furnish a soil congenial for the deposit of the tubercle-bacillus. That its exciting cause is often a fall, a wrench, or other injury to the joint is true, yet the disease never follows such traumatism in perfectly healthy children. In some cases it occurs without any assignable cause, not infrequently in those who have been confined to their beds for months.

In the vast majority of cases in children under six years of age the disease begins in the bone. Some surgeons look upon the ligamentum teres as the point of primary disease, but post-mortem examinations entirely disprove this theory. The hip-joint differs in two respects from any other articulation: first, the epiphysis and neck of the bone are entirely within the capsule of the joint; secondly, they are more isolated, and the supply of blood is more easily interfered with, than in any other articulation.

The disease has been divided into the femoral, the acetabular, and the synovial variety, according as the affection starts in one or other of these localities. But, whether it begins in one situation or another, its course, if not relieved, is slow and progressive until every structure in the joint is involved. It may begin in any portion of the bone, but usually begins in the head or neck,—not so frequently in the acetabulum.

As in other articulations, the tubercle follows one of three courses: it may infiltrate the bone, showing no tendency to become limited; there may be one or several foci surrounded by inflammatory exudation, which gradually break down, unite, and form tubercular abscesses of varying size, which may gradually, by absorption, inflammatory softening, or necrotic or carious changes, reach the outer shell of the bone and finally gain access to the joint; or the deposit may undergo a cicatrizing process, and recovery take place without any direct implication of the joint. According to the course pursued by the deposit will be the rapidity of the joint-infection or the tendency towards a cure.

In the first or infiltrating variety of tubercular infection, the joint is soon affected. These are the cases in which the disease advances so rapidly that its progress resembles that of malignant disease. The whole end of the bone becomes infiltrated, the inflammatory process often extends down into the shaft, and the patient soon dies of general exhaustion from the effects of deposits in other portions of the body.

In the second variety, in which the disease is at first limited to certain parts of the bone and surrounded by inflammatory deposit, whether bony or fibrous, its course is much slower. It may be months or even a year or more before the pus gains access to the joint. The contents of the abscess may infect the limiting exudation and the bone be again infected from this point, so that the neck and head of the femur may become infiltrated as in the first variety, and the disease from this point pursue a rapid course. In those cases where the abscess slowly works its way to the surface of the bone, it often discharges through a small sinus either in the neck or through the articular cartilage. Within these cavities are frequently found sequestra of varying size. In the cicatricial variety the joint is never infected, and a cure takes place often with perfect motion. But all these varieties run into one another.

The factors which determine the course of the tubercular deposit, whether towards infiltration, a local necrosis, or cicatrization, are the amount of primary local infection, the general physical condition of the patient, and treatment. Recovery from bone-tuberculosis is always by the substitution of connective tissue for the tubercular. If, therefore, an abscess-cavity has formed, its contents must have been removed and replaced by connective tissue before recovery can take place; and this is always a slow process.

The appearance of the bone in hip-joint disease depends upon the variety and the stage of the affection. In the infiltrating variety the bone is filled with inflammatory products; the cancellous tissue is soft, spongy, and easily broken down under the fingers; the bone is of a dirty dark-red color; the periosteum is thickened and easily stripped off, exposing the surface of the bone, of a dark color. The articular cartilage is changed: sometimes it is detached in a mass; at other times the epiphysis lies loose in the joint-cavity, covered more or less with cartilage; again, there may remain islets of cartilage surrounded by granulations from the bone; in other cases it presents a worm-eaten appearance, with granulations protruding from the bone beneath. The synovial membrane is thickened, velvety on its inner surface, and perforated. The joint has become affected early, and is found filled with sanious pus, bony detritus, and sequestra. The trochanter major is often easily detached from its connection with the shaft. In fact, every tissue about the joint has become diseased. The same condition is seen in those cases that have advanced to total destruction of the part although the disease may have started as a local affection in the bone, the cancellous tissue having been infected from one or several small foci. In those cases where an abscess has formed and perforated the bone, forming an opening of varying size, the bone may never exhibit such extensive disease as mentioned above. There may be more or less loss of substance about the head and neck: thus, its upper segment may be destroyed, or the lower portion, with the under surface of the neck, may be deeply eroded; the inner portion of the head may be destroyed, leaving a shell of bone, the cartilage may show necrotic change, or there may be found only a sinus leading into a small cavity in the head or neck, the joint itself showing but a slight amount of disease. In fact, between these two extremes every shade of difference is found.

In cases of advanced disease the epiphysis may be entirely destroyed or may be detached and lie loose in the joint. Later in the disease nothing may remain but the truncated end of the neck, the joint being filled with sequestra of varying size, sometimes representing the entire head of the bone denuded of cartilage and filled with granulations.

When the disease has existed for some time and is extensive, we may find that it has extended down the shaft as a chronic osteomyelitis. The appearance of the cut surface of the bone is characteristic; its compact tissue is greatly thinned at the expense of its inner shell, its color is dark, and the medullary cavity is filled with a soft, dirty yellowish-red material. The periosteum is easily stripped, so that the whole diaphysis can be extracted from its covering by simply pushing it up, leaving the periosteum intact. Sometimes the head and neck may be found detached; in such cases the end of the shaft is irregular and looks dark, with diseased medulla protruding from its central cavity. If a section is made lower down, the same condition will be found: the whole diaphysis is involved.

Disease may begin in the floor of the acetabulum: in these cases perforations may take place early. Recently there has been under my care a child, four years of age, who when first seen was supposed to have tubercular osteitis of the head of the femur. The spasmodic contractions of the muscles of the thigh were very frequent both day and night, and absolute rest and extension failed to relieve them. I therefore trephined through the trochanter major. This did not relieve the spasms, and I opened the joint, as there was evidence of pus in it. The articulation was found full of pus. The cartilage on the head was bright and apparently healthy. The acetabulum was extensively diseased, its floor was perforated, and there existed an intrapelvic abscess of considerable size. The head and neck were removed in order to afford drainage to the pelvic abscess. On section of the head it was found not involved in the disease. Cases are upon record in which the head and neck of the femur have passed into the pelvic cavity through the acetabulum, so extensive has been its destruction. Sometimes the primary focus of disease has been in the rim of the acetabulum.

In advanced disease changes in the shape of the acetabulum are often found; its upper portion is eroded, so that what remains of the head and neck of the femur occupies a higher plane than normal. Among the older writers we often find mention of dislocation of the head of the bone as a common result of chronic disease of the hip-joint. This is an error, probably due to the lack of post-mortem examinations. In the later stage of hip-joint disease the head is often flattened or destroyed in its upper segment; the action of the muscle is to draw the whole bone upward and backward, so that the upper border of the trochanter is placed upon a higher level than normal; at the same time the upper border of the rim of the acetabulum is eroded. Either or both of these conditions permit the trochanter to assume a position above Nélaton's line and thus simulate dislocation. True dislocation, however, is occasionally met with. When early in the course of the disease the ligamentum teres has been destroyed, and there is marked flexion and adduction, the head of the femur may be forced out of the cavity of the acetabulum by muscular action. Some years ago a child was under my care with double hip-joint disease. On examining the patient one day it was found that the head of the bone upon one side could be thrown out on the dorsum and readily replaced. On post-mortem examination a few weeks later (the patient having died from uræmia), it was found that the ligamentum teres had been destroyed and that the head could easily be displaced upon the dorsum of the ilium. Gibney, in his work upon "Disease of the Hip," mentions having met with two cases of this complication.

Disease beginning in the trochanter major is mentioned by Annandale, Erichsen, and others. I have never met with it, and judge that in children it is very uncommon, from the fact that the trochanter is mainly cartilaginous until near puberty. The contents of a tubercular abscess in the neck of the femur may open outside of the capsule and the joint not become implicated, the condition being similar to an abscess in the condyles of the femur which has opened laterally and not towards the articulation. In such cases there may exist a cavity containing a sequestrum, a sinus discharging more or less pus being present. Hip-joint disease may begin in the synovial membrane, but more frequently begins in the bone. In the knee, on the other hand, tubercular inflammation of the synovial membrane is as frequent as that starting in the bone. Not long since, I had occasion to open a hip-joint in a child of six years, and found it filled with the granulations so often seen in tubercular synovitis of the knee-joint; the cartilage was only slightly affected, and there was no apparent disease of the bone, but the joint-cavity was filled and distended with this characteristic granulation-material and the capsule thickened. Gibney, although convinced of its occurrence, has never been able to prove it pathologically. If the disease advances, a time comes in the pathological history of the affection when the cartilage will have become perforated and more or less destroyed and the bone involved in the disease, so that on opening such a joint it will be impossible to state in what particular structure the disease began. Practically, so far as treatment is concerned, it makes no difference whether the affection has its origin in the synovial membrane or in the bone, and it is often impossible clinically to separate the two conditions.

Hip-joint disease may be divided into three stages. The first corresponds to the period of osteitis, the disease being limited to the bone; the second, to that in which the joint becomes infected; the third, to the perforation of the capsule, the formation of abscess in the soft parts, and the total destruction of the articulation. The first stage extends from the time of the deposit of tubercle in the bone to the time when the joint becomes infected, and pathologically corresponds to the period of osteitis. Its duration is variable, from a few months to a year or more, according to the acuteness or chronicity of the affection. Its symptoms are lameness, pain, altered position, limited motion, and muscular wasting. While in its later stage hip-joint disease is easy of diagnosis, its earlier symptoms are often overlooked or misinterpreted; yet if they are properly appreciated they are as distinct and convincing as those of the second or those of the third stage. The symptoms will now be examined in detail.

SYMPTOMS.

Lameness.—One of the earliest and most constant symptoms of hip-joint disease, coming on often before the patient complains of any pain, is lameness. This lameness is peculiar. There is an element of stiffness about it. It may be only a slight favoring of the affected limb, a little awkwardness; the foot is not raised so high, and the step is shorter. The child seems to be careful of the limb. There is stiffness in the morning and the limp is then more marked, but diminishes after use of the limb. In other cases it may be in the evening that this symptom is most noticed. But, through all, the patient, although not complaining, seems to be careful of the limb. He does not stand upon it. This condition may continue for weeks or months; there may be times when lameness is more marked, a day or so, or even a week; then it will decrease, and the patient go about as before. There is something peculiar about this limp which is almost pathognomonic of the disease, and, although careful examination may not detect any other symptom, yet it is too often the forerunner of more pronounced and decided signs. With this condition of the limb there may be found slight flexion. It is a rule that persistent lameness or stiffness of a limb should always be looked upon with suspicion, and it is not to be lightly dismissed, for it is too often the first symptom of joint-trouble.

Pain varies greatly in amount: sometimes it is slight, at other times severe from the beginning. Sometimes it begins with the lameness, at other times it may be absent or almost absent for months. It may be referred to the hip or to the anterior and lateral parts of the thigh, but it is most commonly at the knee and front of the thigh, so that hip-joint disease is often mistaken for disease of the knee, and splint and blisters have been applied for disease of that articulation. Sometimes the pain is referred to one spot, as the inside of the knee or in front, but most frequently the patient cannot exactly locate it except that it is in the knee. There may be diffuse pain down the thigh. I have now a case under treatment in which the pain is in the course of the sciatic nerve. At times it is referred to the leg, or even to the foot. Pain is often so slight that the parents of the child will deny its existence. At other times it will overshadow all other symptoms; it may come and go; it is often attributed to "growing pains." It may come on suddenly while the patient is taking exercise, and be so severe that he will grasp the knee and cry out from suffering. There is one peculiarity about hip-joint disease: it is liable to exacerbations during which the pain and lameness are more pronounced; a fall or over-exertion may develop it; after rest for a short time the more acute symptoms remit, and the child's condition returns to that previous to exacerbation. In other cases pain will be marked almost from the first, the pain and lameness going together. Thus pain may be only an occasional or passing symptom, may be detected only on passive motion, or may be violent even when the patient is at rest. The child will grasp the knee in order to steady the limb and thus relieve the suffering. These reflex pains are always in the course of the obturator and anterior crural and sciatic nerves. In some few cases pain is complained of in the joint itself. Pain is, as a rule, increased by pressure over the trochanter, in front over the capsule, or behind the trochanter major in advanced cases. In the course of the disease, in some cases earlier than in others, the patient is subject to painful startings of the limb at night; often as he is going off to sleep he is roused by starting of the limb accompanied by acute pains, so that he will wake up with a cry, or it may come on during deep sleep. The child will not be thoroughly roused, but will cry out. This soon passes off, but it may in time be followed by another attack, and this may be repeated many times during the night. The cry is so characteristic that it has been given the name of "osteitic cry," and, when present, is pathognomonic of joint-disease. It is caused by spasmodic contractions of the muscles of the thigh, which crowd the inflamed parts together. These painful startings may continue for weeks or months; they sometimes occur only during an exacerbation, or they may be more frequent at that time. Later in the disease lameness and pain may be almost constant.

Altered Position.—In the early stage of the disease the limb at first may be only slightly flexed; later this is more marked, and abduction and rotation outward are added. This is the position of lengthening of the older writers. The position is one of greatest ease. "Flexion relaxes the ilio-femoral ligament in front of the joint, abduction the ligamentum teres and the upper band of the ilio-femoral ligament, and rotation outward the inner band of the ilio-femoral ligament and the back of the capsule" (Marsh). Early in the disease changes take place in the shape of the fold of the nates, and there is flattening of the buttocks on the diseased side, due to actual flattening or relaxation of the gluteal muscles; abduction and rotation may also be an element in its causation. If one examines a child affected with hip-joint disease, it will be found that the fold of the nates is lower and that the buttocks are wider and more flabby on the diseased than on the sound side. If there is much flexion, while the patient is standing, the anterior curve of the spine in the lumbar region will be found increased (lordosis), due to arching forward of the lumbar spine in order to compensate for the flexion of the thigh. The explanation of this position and of the apparent lengthening of the limb in this stage and of its shortening in the later stage is clearly stated by Marsh as follows:

"As the patient cannot use the limb for progression when it is either flexed and abducted or flexed and adducted, he adopts certain compensatory positions which enable him to move about. Having lost the power, through stiffness of the hip, of moving the femur on the pelvis, he now moves the femur and pelvis together. By curving the lumbar spine forward (lordosis) he turns the pelvis on its transverse horizontal axis, so that the knee points downward. To compensate for the abduction (Fig. 5), he draws up the sound side of the pelvis (Fig. 6), and thus depresses the affected side, with the result of bringing the femur inward towards the middle line. This movement, attended with curvature of the lumbar spine towards the diseased side, has by lowering that side of the pelvis the incidental effect of producing apparent lengthening of the affected limb (Fig. 6). If the limb is adducted (Fig. 7), the reverse occurs: the patient draws up the pelvis on the affected side, and so wheels the limb outward. This movement is attended with curvature of the lumbar spine with its concavity towards the diseased side and incidental apparent shortening (Fig. 8). This apparent lengthening is invariably the equivalent of abduction, and apparent shortening of adduction."

Fig. 6.

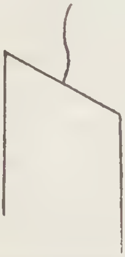

Diagram illustrating apparent lengthening. (Marsh.)

Fig. 7.

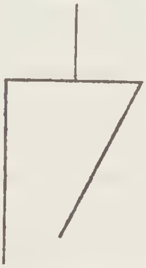

Diagram showing adduction. (Marsh.)

Fig. 8.

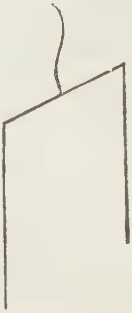

Diagram illustrating apparent shortening. (Marsh.)

Real shortening does not belong to the first stage.

Limitation of motion is the most invariable, and, taken alone, the most conclusive, symptom of hip-joint disease. Its absence, except in the very earliest stage of the disease, is almost proof that hip-disease does not exist. In order to appreciate this symptom certain precautions and methods must be followed. The child's clothes should be entirely removed, and, after satisfying one's self that no disease of the spine exists, he should be laid upon a firm couch or some flat surface, so that the outline of the spine and limbs can be seen. The anterior superior spines of the ilium must be placed upon a level: normally, when a child is placed in such a position, the lumbar spine, the posterior aspect of the thigh and leg, and the heel should touch the couch; any change from this position is pathological. If, while the knee is down upon the couch, the lumbar spine, when the finger is placed under it, is found to be arched forward, flexion of the thigh upon the pelvis exists: the amount of flexion is ascertained by raising the thigh until the lumbar curve is obliterated; the angle which the thigh makes with the long axis of the body denotes the amount of deformity. Placing the iliac spines upon a level, the amount that the affected limb deviates in the direction either of abduction or of adduction from a line passing from the notch of the sternum through the symphysis pubis denotes the amount of abduction or adduction present, or, what amounts to the same thing, moving the suspected thigh outward or inward until the anterior superior spines of the ilium are level.

Having thus determined the presence or absence of flexion, abduction, and adduction, the amount of motion at the hip-joint should be tested. With the knee a little bent, first flex while you abduct or adduct the sound limb to its fullest extent, in order that any slight deviation from the normal may be detected in the suspected one; next carry the suspected limb up on to the abdomen towards extreme flexion, and note carefully whether there is any resistance or pain (the sound limb being kept flat on the couch). Do this gently; never use force. Then test the movements in other directions, —abduction or adduction, whether inward or outward,—and note the presence or absence of resistance. As soon as the limb is grasped it will be found that the slightest resistance can be appreciated. If flexion is limited, no matter how slightly, even if the other movements of the joint are normal, hip-disease in its early stage must be suspected; if in addition motion is limited in any other direction, the inference is almost certain. Next to flexion, limited rotation is an important symptom; but resistance in any direction has the same value.

The joint must now be tested as to its sensitiveness and smoothness of motion; this should be done with the greatest gentleness; the old method of striking the sole of the foot to find out if there is any pain in the joint is as useless as it is barbarous. If there is disease about the hip, such methods are sure to aggravate it.

Limited motion is not peculiar to hip-joint disease; certain conditions outside of the articulation may cause it. Thus, a psoas abscess, an inflamed bursa, a gluteal abscess, or disease of the upper end of the femur, may prevent free motion. In such cases Marsh advocates the following method. "Flex the limb to an angle of one hundred and twenty degrees with the trunk: if rotation is unimpaired, so that the smooth head of the femur turns freely in the acetabulum, it may safely be concluded that the loss of other movements depends upon some condition external to the joint, while if rotation is deficient it will tend to show that the joint itself is affected." I do not think, however, that this test is as reliable in the early as in a later stage of the disease.

Muscular wasting is a very constant and important symptom, but it varies much in different cases. Sometimes it comes on early and is marked; at other times it is later in its advent, but, as a rule, some muscular atrophy is present among the earlier symptoms. It escapes notice because not carefully looked for.

Atrophy may be noted early and be marked, or may be slight until the second or third stage of the disease is reached, but it is almost always present; it may be detected by comparing the two sides, by the flabbiness of the muscles of the affected limb, or by actual measurement of the two limbs upon the same level. During the exacerbation the atrophy is apt to increase more rapidly (Gibney). In the second and third stages of the disease it is marked, so that the bones seem to be covered only with skin.

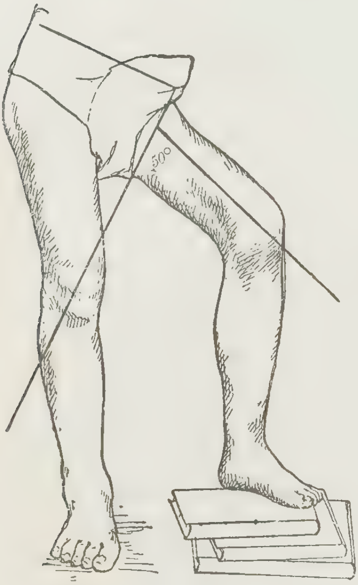
These symptoms,—lameness, pain, limited motion, muscular atrophy, osteitic cry,—taken together, make up a group which, when present, can leave no doubt as to the existence of serious joint-disease. In the early stage many of them are absent, but a history of persistent lameness, no matter how slight or how intermittent, with muscular resistance to passive motion, points almost conclusively to osteitis in the head or neck of the femur, and unless the disease is checked the other symptoms mentioned above will follow, and these constitute what is called the first stage of the disease. The time that these signs may continue without any apparently marked change is often measured by months or even a year; there may be but little to draw one's attention to the joint, beyond a slight limp or an occasional attack of pain, so that one is sometimes at a loss to account for the lameness.

Pathologically the first stage corresponds with osteitis of the head or neck of the bone before the joint becomes infected. There may, however, be attacks of pain accompanied by an increase of fluid in the capsule due to irritation, but it is not purulent, at least at first, nor tubercular. The early attacks of synovitis pass off after a few days' rest, but if they are frequent, and the bone-abscess is approaching the free border of the bone, the effusion may not pass off, but persist, and the joint be permanently enlarged. Exacerbations are not uncommon, during which the pain, tenderness, and limping will be increased for a time; with these the joint will also be found to be swollen; after rest for a few days these symptoms will subside, the parts will return to their former condition, and the disease will pursue its old course. An exacerbation may be brought on by a fall or by over-exercise. If one sees a patient first during one of these exacerbations, he may be mistaken as to the stage of the disease, thinking that it is more advanced than it really is.

The second stage corresponds pathologically to the extension of the tubercular disease from the bone to the joint. The articulation may have suffered from serous effusion during the first stage, but in this it is actually infected. This stage may come on slowly, the lameness, muscular spasms, and pain gradually increasing, the joint becoming more fixed, and the limb more useless; or these symptoms may suddenly become more marked, the limb being held fixed, and the patient suddenly developing marked and persistent lameness. In this stage the joint will be found to be swollen, either in front of or behind the trochanter major, and at a later period abscess may be discovered starting from the back of the joint or in front. All the symptoms of the first stage are increased: muscular spasms at night are more frequent, and the child shows in his face the effects of his suffering. During this stage abduction is often changed to adduction; yet there is no rule about it; but we generally find the limb apparently shortened, considerably flexed, and fixed. Later, abscesses appear, and actual shortening begins to show itself.

The third and last stage of hip-joint disease corresponds to changes in the bone, real shortening, the increase of abscess, and total disorganization of the joint. The limb is now fixed, strongly flexed, and adducted and rotated outward, although in a few cases the opposite is found, due probably to position in bed, the patient keeping the limb flexed, rotated outward, and adducted. (Fig. 9 illustrates a case under my care.) This is the stage of true shortening, due to actual loss of substance in the head and neck and elongation of the upper border of the acetabulum. To this may be added atrophy of the bone from disuse. There is hardly any limit to the changes that may take place in the bone in this stage,—the head and neck gone, the acetabulum perforated, the pelvic bones involved in disease, and abscesses burrowing in almost every direction.

Fig. 9.



A case of abduction. (Poore.)

Abscess.—There are but few cases of hip-joint disease which have advanced to the third stage in which the pus does not perforate the capsule and appear among the muscles. The symptoms of the formation of abscesses are often vague and obscure. It is stated by some that they give no warning of their advent. This is an error, for, although the signs may not be marked, yet, if careful inquiry be made, one will get a history of increased pain, more restlessness at night, and less inclination, if the patient is up, to move about, occurring some weeks or months before the discovery of the abscess. If at the times when the child exhibited this increased pain a careful examination had been made, a fulness might have been detected either behind the trochanter or in the joint in which the abscess began. In some cases the symptoms of the formation of an abscess are increased pain, a rise of a few degrees in the temperature, a fulness in the upper part of the thigh, and a decline in the general condition of the patient. Acute abscesses may also be found in connection with chronic disease of the hip. An increase in the size of the thigh is almost positive proof of the existence of an abscess. All abscesses do not come to the surface. Suppuration may take place in a joint and even perforate the capsule, yet by absorption and caseation the fluid contents may disappear, giving no further trouble, or reappearing at some future day as a residual abscess.

The thermometer is not a reliable guide as to the formation of abscesses in connection with this disease unless they are acute. They then give the same symptoms as similar abscesses in other parts of the body. In some cases I have found a slight elevation of temperature in connection with increased restlessness at night and pain, which has denoted the commencement of an abscess, or rather its extension, and would therefore consider an evening elevation of temperature suspicious and probably as pointing to increased suppuration. That some of these abscesses form very slowly and give no indication by any increased temperature is also certain, so that the absence of fever is not a proof that an abscess is not forming.

When abscesses are small and deeply seated, they may be detected by the presence of deep-seated resistance to pressure or of a circumscribed swelling about the joint. When formed in the joint-cavity, the pus may after perforating the capsule burrow in various directions: it may perforate the capsule in front just below Poupart's ligament, and may then travel down the thigh, or follow the sheath of the psoas muscle into the pelvis and discharge through the rectum; it may pass out of the joint posteriorly, and burrow beneath the gluteal muscles or down behind the tensor vaginæ femoris, appear in the perineum, or enter the pelvis along the track of the external rotators: in fact, it may follow the plane of any of the muscles and come to the surface far from the joint. In cases of long standing when the bones are profoundly diseased, abscesses may open in many places, so that the skin about the hip will be undermined and riddled with sinuses, which continually discharge unhealthy pus. Abscesses sometimes form within the pelvis from disease of the floor of the acetabulum, or enter it from the joint through a perforation of that portion of the pelvis. Intrapelvic abscesses are outside the obturator fascia; the pus makes a cavity for itself by stripping this membrane from the bone. When these collections of matter are of any size, they may be detected by rectal examination. The course of these intrapelvic abscesses is various; as they enlarge they may come forward, and can be felt under and above Poupart's ligament or by dipping the finger down from above into the pelvic cavity; they may open into the rectum or bladder; or they may come down the psoas muscle. Whatever may be their course, they are serious complications, not only from the difficulty of draining them, but also from the fact that they denote disease of the pelvic bones.

Thickening of the trochanter major is considered by many writers a most certain indication of suppuration within the joint. In order to appreciate it, the trochanter should be grasped between the fingers and thumb and compared with that of the sound side; if thickening is present it will, with one or two exceptions, be always found that there is pus in the joint. The exceptions are cases of spinal, sacro-iliac, or pelvic abscess which have burrowed down around the trochanter, and cases of disease of the upper end of the femur, etc., outside of the joint.[1] Barwell mentions the same symptoms.

When destruction of the joint has taken place, grating may be discovered in some cases. Its presence is a certain sign of the existence of diseased bone. Yet there are many cases in which, though the cartilage on the femoral and pelvic portions of the joint is destroyed, crepitus cannot be produced, from the fact that the denuded bones are separated by granulations springing from the capsule and bone, or from the fact that only one part of the bone is denuded.

---

[1] Wright, op. cit., p. 57.

Quiet Disease.—There is a form of hip-joint affection which Marsh describes under the name of "quiet disease," not infrequently met with. These cases are characterized by an absence of some of the most prominent symptoms of the disease as usually met. They are liable to be overlooked by both parents and physicians until the joint has been completely crippled. There is no pain to attract attention, no tenderness, and but slight swelling. The main symptom is slowly-increasing stiffness. Children are often seen who have been brought for advice not because of any pain, but because the joint has become stiff, the child going about without any inconvenience except lameness from inability to move the articulation. In other cases the symptoms are a little more marked, yet not enough to cause much complaint. The children are brought because of some swelling about the thigh, and on examination an abscess is found, and perhaps disorganization of the joint. Between these cases and those following the more common course there is every shade of difference. It must be remembered that the amount of pain and discomfort varies greatly in different cases. In some the suffering is severe almost from the very commencement of the affection, while in others the amount of discomfort is slight. In both classes the disease tends to go on to total destruction of the joint.

DIAGNOSIS.

The diagnosis of hip-joint disease in its advanced stages is based upon a set of symptoms which taken together form a picture that leaves us in no doubt as to what we have to deal with. In its early stage it is often extremely difficult to arrive at a satisfactory conclusion from the few symptoms present, owing to their apparent variableness and often to our inability to obtain a reliable history of the patient from want of observation and often ignorance of the parents. As stated before, persistent lameness, or even a history of transient lameness coming on after exercise, persisting for some time, and then passing off, to reappear again under similar circumstances, or a certain stiffness in the morning, disappearing in a few hours, only to be found again the next day, is not to be treated slightly. If pain is added to this, no matter how slight or how intermitting it may be, we have an additional proof; and if with this there is resistance to passive motion, we have all the symptoms that go to make up the first stage of hip-joint disease.

This stage may last for months, or even for a year or more, so that the parents or even the surgeon may think that an error has been made, and if treatment has been begun it is sometimes abandoned, and one realizes the mistake only when an abscess is discovered and it is suddenly found that other and more profound symptoms have made their appearance. The early diagnosis of hip-joint disease is of great importance, for by treatment we may hope to cure the affection in the bone before the joint has become involved.

There are certain diseases which may be mistaken for hip-joint disease, or for which it may be taken. These are muscular rheumatism about the hip, bursitis, contusions or sprains, neuroses of the hip-joint, infantile paralysis, perinephritis (Gibney), vertebral osteitis, sacro-iliac disease, and congenital dislocation of the hip-joint.

Muscular rheumatism from cold and over-fatigue gives symptoms that may cause it to be mistaken for hip-joint disease. The suddenness of the attack without any premonitions, the helplessness of the patient in locomotion, the acuteness of the pain on active movement and its absence or great mitigation when the patient is at rest, with the absence of tenderness and atrophy of the limb, give a history that does not belong to articular osteitis. The pain and lameness come together; the motion at the hip is free and smooth, with no muscular resistance.

Bursitis.—There are certain bursæ about the hip which sometimes become inflamed and simulate disease of the joint. Thus, a large one lies between the tendon of the iliac and the capsular ligament; it often communicates with the synovial cavity. Between the gluteus medius and the trochanter major is a small bursa; there is one of large size between the tendon of the gluteus minimus and the front of the trochanter; another between the gluteus maximus and the vastus externus, over which rides the strong fascia of the buttock; one also between the gluteus maximus and the trochanter major. These are the principal bursæ. The cause of bursitis may be a fall or sprain and cold (Gibney). The symptoms are some pain and tenderness referred to the location of one of these bursæ, an absence of pain and muscular resistance on passive motion, and a marked swelling in the situation of the bursa.

Contusions and sprains about the hip have been mistaken for hip-joint disease. The history of a fall or sprain, the rapid appearance of the pain, and the acuteness of the attack, should prevent the error.

Neuroses of the hip-joint are not infrequent, and present one of the most difficult problems in diagnosis, and in some cases it is impossible to separate the two, for there may exist disease of this articulation with marked neural symptoms. Hysterical joints are found among young children as well as in adults. Patients with hysterical joints always belong to neurotic families. The pain complained of will be out of all proportion to that due to disease of the hip-joint. There is marked hyperæsthesia of the skin about the joint, or, it may be, of the whole limb; there is often tenderness upon pressure over the spinal processes of the lumbar vertebræ; there may even be swelling about the joint (Gibney). Notwithstanding these symptoms, the limb, as a rule, looks plump and well nourished. There may be, and often is, fixation of the articulation, but, if the patient's attention is drawn off while the examination is being made, the limb can be freely moved, and that without any pain. The starting-point of a neurotic affection of the hip-joint may be an injury, and the pain and lameness come on together, and are more acute, according to the patient's statement, than is the case in true hip-joint disease. The limb is flexed and often cold and blue. These patients do not complain of pain at night, as in disease of the hip-joint. The surface of the joint is often exquisitely sensitive to the touch. This is not found in articular inflammation. These exaggerated sensations and the general condition of the patient—the plump and healthy appearance—should be relied upon to separate neurotic affections from true hip-joint disease.

Infantile paralysis should never be mistaken for hip-disease: the acute onset of the symptoms, often with fever, the absence of spasm or contraction of muscles, the free motion of the joint, and later the marked atrophy in certain muscles, as well as the absence of pain, and the coldness of the whole limb, should prevent it from being taken for any joint-affection.

Periarthritis (Gibney) is not a common affection. Cellulitis among the muscles is an acute affection accompanied by local pain and marked constitutional symptoms, but it does not present the signs nor run the chronic course of articular inflammation.

Vertebral caries is more often mistaken for hip-disease than any other lesion, especially when the lumbar portion of the spine is affected. The pain may be referred to the knee, thigh, or hip-joint; there may be present marked lameness, with flexion of the thigh on the pelvis, especially if there is an abscess in the psoas muscle; there is atrophy of the limb. A child with vertebral disease can stand as well upon the suspected limb as upon the sound one; there is a stiffness in his carriage that is not seen in hip-joint disease; there is an absence of reflex spasms of the muscles of the thigh; the patient suffers greater increase of pain when he assumes the erect position and experiences more relief when in the horizontal position than in coxitis. On passive motion the head of the femur moves smoothly, and there is no muscular resistance except when the psoas is involved. When deformity of the spine is present there can be no question as to the diagnosis. It is a rule always to examine the spine in all suspected cases of hip-joint disease. As to the more special symptoms of spinal disease the reader is referred to the article upon that subject.

Disease of the Sacro-Iliac Joint.—Disease of this articulation may simulate hip-joint affection. Gibney questions its existence except as a secondary affection. It would seem that the question whether it is a primary or a secondary affection turns upon the fact whether disease beginning in the bone just beneath the cartilage is to be considered primary or secondary disease of an articulation, and whether disease ever begins in the articulation itself. Marsh[1] records a case in which the joint was in a condition of "pulpy thickening" and was bathed in "curdy pus." Barwell considers that some of these cases are low-down Pott's disease. Van Hook[1] has collected cases of tubercular disease of this articulation occurring in childhood. It would seem that disease beginning in the bone just beneath the cartilage holds the same relation to the joint as hip-joint disease beginning in the head or neck of the femur, and, although in these cases the joint is secondarily affected, we practically consider articular osteitis a joint-affection. The same rule should apply to disease of the sacro-iliac joint beginning just beneath the cartilage, while cases of low-down Pott's disease which has extended to this joint may be looked upon as secondary.

---

[1] Op. cit., p. 366.

That the cartilage, or rather that tissue in the sacro-iliac synchondrosis which represents a synovial membrane in other articulations, may be the seat of disease, is accepted by surgeons. But, whatever view may be adopted, the fact that there is an affection in or about the joint between the sacrum and the ilium which may be mistaken for disease of the hip is universally admitted. Marsh states that "it is probably for the most part scrofulous in its origin, but it is sometimes the result of injury in previously healthy subjects. . . . The changes that occur in the articulations may involve mainly the synovial membrane in the form of chronic inflammation and pulpy degeneration resembling that which is met with in the knee and other joints. In other cases the bones appear to be the parts that are first attacked,"[2] while in still others the disease extends from disease of the pelvic bones or the sacrum. There are, therefore, two classes of the affection, one in which the disease begins in the joint itself, or in close proximity to it, the other where the disease has extended to the articulation from some distance. But in whatever way the articulation has become affected, abscesses in time form, either within or external to the pelvis or in both localities, and the joint becomes completely disorganized. If an opening has been formed or is made to evacuate an abscess, it will be found that a probe can be passed into and through the joint. When abscesses have formed, if they are intrapelvic they may make their way down to the thigh or backward, if extrapelvic they appear as a swelling over the articulation.

The symptoms of sacro-iliac disease are variable, and apt to be confounded with those of affections of the hip or of the spine. They are pain, lameness, swelling, and abscess, and some writers add alteration in the shape of the parts.

Pain is a constant symptom, and is usually well marked; it is often severe, especially when the patient bears any weight upon the affected side, or on any motion communicated to the joint; in some cases, however, only a sensation of uneasiness or discomfort is felt about the parts. The pain may be in the joint or may be referred to a distant part; in the latter case it is down the limb in the distribution of the sciatic or the anterior crural nerve, thus simulating hip-joint disease.

---

[1] Annals of Surgery, 1888, vol. viii. p. 401.

[2] Op. cit., p. 301.

Lameness is always met with; early in the disease it may be slight; the patient complains of a feeling of insecurity about his hip, or it may appear only after exercise; in marked cases locomotion is impossible. In standing, the whole weight is thrown upon the sound limb. There is tenderness on pressure over the joint, and sometimes there is a diffuse tenderness over the whole gluteal region. There is in time some swelling over the joint, depending upon the amount of suppuration present. In the early stage a slight swelling directly over the articulation may be discovered on careful examination. Alteration in the shape of the hip is mentioned by many, due to extrapelvic abscess, and later in the disease to atrophy of the muscles. The motion at the hip-joint is smooth, free, and painless if care be taken that no motion is conveyed to the sacro-iliac joint. There may be some flexion if there is a psoas abscess. The thigh is usually fully extended, and there is no shortening.

The diagnosis between this disease and that of the hip-joint requires much care. Lameness is common to both affections; the pain often simulates that of disease of the hip. If, however, pressing the two iliac bones together or apart from each other, or trying to tilt the ilium on the suspected side upward or downward, the hip-joint not being fixed, causes pain, this points to the sacro-iliac articulation as the location of the trouble. Free, painless motion at the hip-joint will exclude that articulation. Swelling in the gluteal region is not positive proof of disease of the ilium, as it may be due to coxalgia: even the presence of tenderness in this region cannot be entirely relied upon. It is only by exclusion that a correct diagnosis can be arrived at. If there is no disease of the hip or lower portion of the spine, and the symptoms mentioned above are found, there is strong probability that the sacro-iliac articulation is affected, especially if pain is caused or increased by crowding the ilii together. The presence of an abscess with a sinus leading into the joint is proof positive of the existence of disease.

The treatment of disease of the sacro-iliac articulation in its early stage is absolute rest to the parts; the patient experiences relief from the application of a firm bandage over the pelvis which holds the parts at rest; extension with a light weight, steadying the thigh and pelvis, may be an advantage. If abscesses exist outside of the pelvic cavity, they should be opened, the diseased tissue removed, the parts thoroughly disinfected, and the wound dressed antiseptically. The management of an intrapelvic collection of pus is more difficult, especially if there is no external abscess; but even here, if one is satisfied that there is disease of the joint, a removal of the cartilage would afford drainage, and frequent washing out with an antiseptic solution might bring about a cure. Van Hook[1] adopted a method of draining an intrapelvic abscess by entering the pelvis through the posterior superior spinous process of the ilium. "The patient lying on the unaffected side, with the thighs in exaggerated flexion on the pelvis, an incision two or three inches long will expose to view the posterior superior spinous process of the ilium, which should be freed from periosteum and tendinous connective tissue by scraping with a blunt instrument; a chisel is then used to remove successive small fragments from the exposed bone, always holding the chisel edge parallel to the spinous process, till the finger can enter the cavity of the pelvis major and palpate the surface of the diseased bone." This would certainly give access to the abscess, and from its position would afford good drainage.

---

[1] Annals of Surgery, February, 1889, p. 126.

If there is much disease of the pelvic bones, however, not much improvement is to be expected from any method of treatment.

Congenital dislocation of the hip should never be mistaken for inflammatory affections of that articulation: the absence of pain, the peculiar walk, the change of position of the head in locomotion, present nothing in common with hip-joint disease. Perityphlitis and perinephritis may sometimes cause flexion of the thigh and pain in the distribution of the nerves having their origin in the sacral and lumbar plexus, from the presence of an abscess pressing upon them; but an examination of the symptoms and a study of the history of such cases will clear up any doubt.

A psoas abscess may open into the hip-joint and set up acute arthritis. It is, however, rare.

TREATMENT.

There are certain wrong impressions held by some in regard to the treatment of hip-joint disease which require a passing notice.

First, in regard to the effect of extension. At one time it was held, and by some it is still believed, that by extension the joint-surfaces are separated from one another. This is an error. Bradford[1] made some experiments upon the cadaver of a child ten years of age, and demonstrated that with one hundred and fifty pounds' extending force applied to the limb, the pelvis being fixed, no separation of the joint-surfaces took place. It is evident from this that in the first stage of hip-joint disease, and until the joint has become disorganized, no separation can be caused between the acetabulum and the head of the bone. The effect of extension in hip-joint disease is to steady the muscles and prevent spasm.

Secondly, in regard to motion. It is claimed by some that by extending the limb by the use of a splint, motion at the coxo-femoral articulation is not only not a disadvantage, but even a positive benefit. In the first place, it is an impossibility so to extend a limb that the joint-surfaces will not be in contact; and, secondly, if it could be accomplished, movement would cause an increased flow of blood to the parts and increase local congestion.

It is a mistake to suppose that the treatment of hip-joint disease differs in any respect from that of disease of other articulations; only its formation makes the carrying out of the general indications in the management of joint-affections different.

---

[1] Boston Medical and Surgical Journal, 1880, vol. ciii. p. 465.

The intelligent treatment of hip-joint disease must be based upon clear views of its pathology.

In the early stage of the affection when beginning in the bone, we have to do with a tubercular deposit in the neck and head of the femur or in the acetabulum. All subsequent changes in the bones and joint have for their starting-point this neoplasm. The deposit follows one of two courses: either it extends and further infects the bone, this extension and infection being accompanied by inflammatory and necrotic changes, or it becomes the seat of connective-tissue metamorphosis and ceases to act as a source of danger. The indications for treatment, therefore, during the first stage are to prevent extension of the disease, and to further the change of the deposit into connective tissue.

In the second stage of the disease the joint has become infected, and we have to do with a tubercular osteitis of the bone and inflammation of the joint. Here our treatment must be directed towards protecting the parts from all sources of irritation, so that repair may be effected by the replacing of the losses from disease by fibrous tissue.

In the third stage, after the joint has become disorganized and the bones necrotic and carious, and abscesses have formed, the indications are to promote the removal of diseased tissue, so that repair can take place.

In disease beginning in the synovial membrane the same indications hold good.

In the constitutional treatment every means should be adopted to improve the general health of the patient. The use of the different preparations of iron, cod-liver oil, and good generous diet, as well as being out of doors in the fresh air and sunshine, if the necessary exertion does not interfere with the local management of the disease, are called for. The indication for the local treatment of chronic tubercular disease of the hip, whether it begins in the bones or in the synovial membrane, is *absolute rest* to the joint, and on this point there is scarcely any difference of opinion among those who have to treat this affection. How best to attain this end has received different interpretations.

In regard to the management of inflammation of other articulations there has always been a unanimity of opinion. Take, for instance, the knee-joint. When it is diseased the method of fixation is well known and always thoroughly carried out. The articulation at the hip differs from that of other joints, except the shoulder, in that a long bone, the femur, is attached to a comparatively short bone, the ilium, so that there is an immense leverage brought by the thigh acting as the long arm of a powerful lever upon the pelvis through the head of the bone as a fulcrum. It becomes, therefore, a difficult matter to keep the joint absolutely at rest. Any device that does not completely fix the joint is so far defective. Take, for instance, the usual method of treatment by weight and pulley as generally applied. When the child is flat on his back the joint is fixed and at rest, but as soon as he sits up in bed movement takes place at the hip-joint in the direction of flexion, and absolute rest is not obtained. A knee-joint would not be considered fixed if, every time the child sat up in bed, motion, even over a small arch, took place; yet this is the condition in the vast majority of cases of hip-joint disease treated by weight and pulley. Every time the child sits up the thigh is flexed upon the pelvis, no matter how much weight is applied. It is said that the flexion does not take place at the hip, but by the bending of the spine in the lumbar region. The deformity in hip-joint disease is always towards flexion; if, therefore, the child sits up in bed, the limb will naturally become further bent upon the pelvis, and motion in the joint will take place. When the disease is treated by a hip-splint of the usual form, in many cases which are not properly attended to, motion is not absolutely prevented, and the joint is not placed in a condition of absolute rest. In the first stage of hip-joint disease beginning in the bone, tubercular foci have formed, and the treatment must be that of similar deposits in other bones. "Among the therapeutic means which exert a beneficial influence on the course of tubercle in bones, absolute rest of the parts holds the foremost position."[1]

This does not mean the application of extension and then allowing the little patient to sit up in bed and twist around all he can; nor does it mean the adjustment of a brace and then permitting the child to go about as much as he wishes or is able. It means *absolute fixation* and rest of the joint, so that *all* motion is abolished and all muscular spasm restrained. This may be accomplished by extension properly applied, and any abnormal position into which the limb has been brought may be as soon as possible corrected.

The deformity in hip-joint disease is in the direction of flexion and abduction or adduction. Abduction, if it is not marked, is not a serious deformity, because it causes an apparent lengthening of the limb by compelling the patient to lower the pelvis on the affected side in order to bring the foot to the ground. Adduction, on the other hand, by forcing the limb of the affected side across the sound one, compels the patient to raise the pelvis upon the diseased side at every step in order to get it out of the way; this is accomplished by the hitching motion so characteristic of the disease; it is also a fatiguing method of walking. Flexion, unless it is marked, is not so maiming a malposition as adduction.

Extension should be applied in the following manner. The patient must be placed upon a hard mattress; the pillow should be small and not raised too high; the trunk must be kept horizontal. The extension plaster should extend well up on the thigh, so as not to drag upon the knee, and should be secured by a smoothly-applied bandage. The child must be prevented from sitting up, and this is best accomplished by the application of a long splint extending from the axilla to the middle of the leg upon the opposite side of the body from that diseased. It is well also to confine the shoulder by a firm band passing around the chest and fastened to the head of the bed. If there exists any flexion or adduction, it should be overcome by applying the extending force in the long axis of the limb as flexed, by raising it upon an inclined plane until the spinous processes of the lumbar vertebræ touch the bed and gradually changing the angle of the inclined plane as the flexion is overcome. To correct the abduction or adduction the limb must be moved outward or inward until the anterior superior spinous processes of the ilium are upon the same transverse plane. The amount of weight necessary to accomplish this is from three to eight pounds, according to the age of the child. By this method the flexion, abduction, or adduction is overcome, and as the deformity is diminished the angle at which the extending force is applied is gradually changed until all malpositions are corrected. The time necessary to accomplish this varies according to the amount of deformity and the length of time that the malposition has existed. This method does not increase the intra-articular pressure; it relieves the spasm of the muscles and gives to the joint absolute rest, thus placing the parts in the best possible condition.

---

[1] Jones, Disease of the Bones, p. 183.

The treatment of hip-joint disease cannot begin too early. As soon as a diagnosis is made the joint must be put at absolute rest. Often it is necessary to hold the pelvis up on the sound side so as to keep it straight. This is done by passing a band around the sound thigh and then carrying one end under and the other over the body and tying it securely to the head of the bed. We thus have an extending and a counter-extending force. It is usual to disregard abduction, as it will take care of itself if the joint retains its use, and if not it is an advantage rather than otherwise. The object of thus fixing the limb is to limit the disease in the bone by allaying all irritation and relieving local congestion of the parts.

The necessity for absolute rest cannot be too earnestly insisted upon. The child should *never be allowed to sit up in bed:* such a position always flexes the thigh upon the pelvis; it also increases the amount of irritation in the parts and thus tends to aggravate the disease. Care should be taken that the foot is kept in a good position,—that is, that the femur is not rotated either inward or outward. This can be accomplished by attaching the weight to a wide board and then binding the foot to it so that it cannot be turned one way or the other, or in any other way that the ingenuity of the surgeon may suggest. In the mean time the child's general health should be attended to, plenty of nutritious food given, and such other means adopted as seem required.

It has been asserted that this confinement to the bed is a great injury to children,—that they grow thin, and that we are encouraging rather than limiting the disease in the bone. I think, however, that the picture is a misleading one. It is astonishing how well children bear this confinement,—how fat and healthy they get, even in surroundings far from healthy, if they are spared the debilitating effects of pain. There is no tonic better than quiet sleep and freedom from pain, and, on the other hand, there is nothing that depresses the health of a child so quickly as sleeplessness and suffering. If absolute fixation of the joint can be obtained and at the same time the patient can have the advantage of fresh air and sunshine, the latter will certainly be no small advantage; but we must be sure that the fixation is obtained, for in the early stage this is of paramount importance.

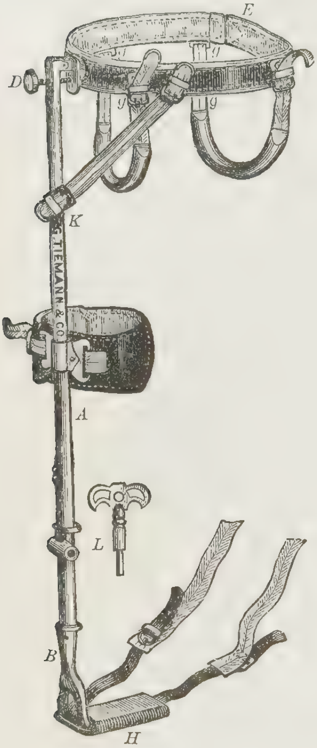
During the second and third stages of the disease the same plan of treatment is applicable: the tendency to deformity should be met by changing the line of traction. If abscesses are detected, they should be treated by the method mentioned in the section on their management.

Some advocate the correction of any malposition of the limb by immediate restitution under an anæsthetic. This method is mentioned only in order that a protest may be entered against the use of any such barbarous means. The deformity is due not to position, but to muscular contraction: in order to rectify the malposition the muscles on one side must be stretched by forcible extension, and to accomplish this the head of the bone must act as the fulcrum and the limb as the powerful lever. By thus crowding the head into the acetabulum injury cannot but be done to the diseased parts, and nothing but an aggravation of the inflammation can be expected. When the disease has been of long duration and when much force has been used, fracture of the femur, or dislocation of the head of the bone on the dorsum of the ilium, has taken place.

Since greater attention has been paid to joint-disease, mechanical ingenuity has been directed towards devising an instrument for the treatment of hip-disease by which perfect fixation could be obtained and at the same time the patient be permitted to go about. The adoption of extension by means of adhesive plaster and weight and pulley pointed out a way by which this end could be accomplished, and the hip-splint, as at present used in this country, is the outcome of the labors of orthopædic surgeons in this direction. To Dr. T. H. Davis is generally given the credit of first conceiving the idea of the present form of hip-splint. Dr. L. H. Sayre soon followed, if he was not contemporary with Dr. Davis. But to Dr. C. F. Taylor is due great credit for his labor in developing the mechanical treatment of hip-joint disease, and the instruments now in most general use are all modifications of the original instrument devised by him. The fundamental principle of a hip-splint is a hip-band encircling two-thirds of the circumference of the pelvis, to which is attached a steel bar extending down below the foot on the diseased side. The splint used by Dr. Taylor is the type of all such instruments. Its form and construction are as follows:

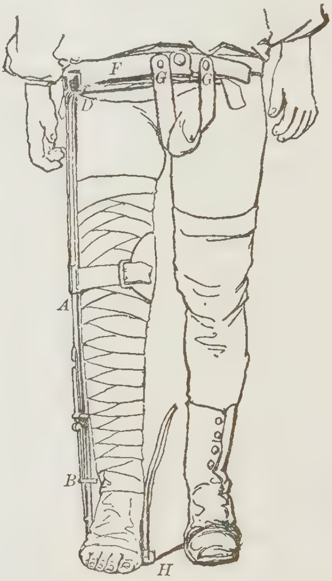
"It consists of a hollow rod of steel (*A*) reaching from the ankle to the hip, with the foot-piece (*B*) working at the lower end and lengthened and shortened by a key which works in a rack on the outside of the lower bar. The upper end is solid and very strong, and is fastened to the pelvis-band by a bolt (*D*). *E* is the pelvis-band, which is made of steel strong enough to support the patient's weight without yielding in the least, and is about two-thirds of the circumference of the pelvis measured over the trochanter major. It terminates in a strap behind, which is fastened into a buckle in front; at *g*, *g*, *g*, *g*, buckles are placed, to which perineal straps are fastened made of flannel covered with kid or some non-irritating material, terminating in pieces of webbing strong enough to hold in the buckles." It will be noticed that the buckles for the perineal straps are close together in front, so that pressure shall not come upon the adductor tendons, and far apart behind, so that the bands may pass under the tuber ischii. *F* is a leather pad to steady and support the knee, and is furnished at *G* with a movable cross-piece. The foot-piece (*H*), the shaft of which extends up into the hollow bar (*A*), passes under the foot. At the lower end of this foot-piece a ridge is left on its anterior and its posterior edge, so as to form a depression through which can pass the strap fastened to the ends of the extension plaster, and thus protect the strap from cutting out. There is also a buckle placed upon the bar at *K*, and another at the hip-band, a strap passing from one to the other, so as to keep the band level.

FIG. 10.



Taylor's splint.

FIG. 11.

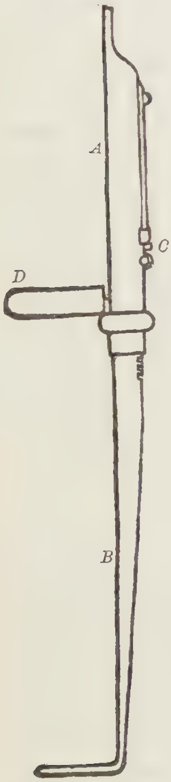


Taylor's splint applied.

The following is the method of applying the splint. Two broad bands of strong adhesive plaster—made for this purpose, and obtainable of any druggist—long enough to extend from the upper portion of the thigh down to the ankle, and having a buckle securely fastened at the lower end of each piece, are prepared. A bandage is then applied over the plaster, so as to hold it securely, a few turns being made under the buckles at the ankle, so as to protect the skin in this locality.

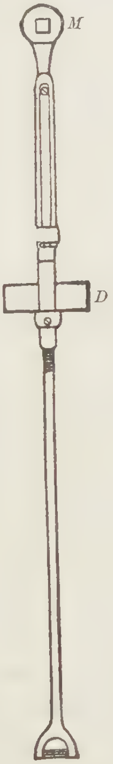
The brace is applied by first placing the patient upon his back, great care being taken that the pelvis is level, so that the limb shall be in its deformed position ; the hip-band is then slipped around the pelvis and fastened, the perineal bands are drawn tightly, and the leather straps under the foot are buckled to the adhesive plaster. The pelvic band should embrace the pelvis below the anterior superior spinous process of the ilium. When all is adjusted, while the patient is on his back, the key, *L,* is turned to the right and the instrument elongated, when the whole leg will be gently but strongly drawn downward. Care should be taken that the splint is applied in the line of *the deformed limb,* not at right angles to the transverse axis of the pelvis, for if the force be applied in the latter direction intra-articular pressure will be produced. The line of extension must be gradually changed until all deformity has been overcome. In order to accomplish this an inclined plane is used, only the splint is substituted for the weight and pulley. Fig. 11 represents the splint applied.

Fig. 12.



Front view.

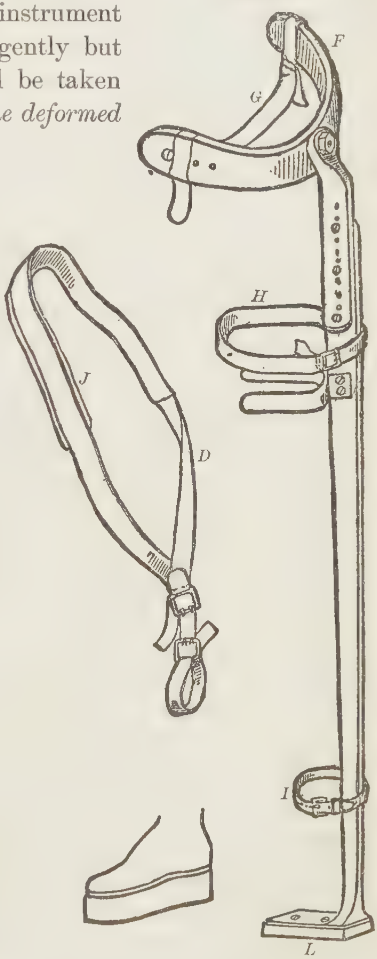
Fig. 13.



Side view.

Judson's splint.

Fig. 14.



Dr. A. B. Judson has modified Dr. Taylor's instrument in some particulars, his object being to diminish the weight of the splint, while retaining its strength. Figs. 12, 13, and 14 represent this instrument. It consists of a hip-band, and an upright extending from the pelvis to the foot (Fig. 12). The upright consists of two pieces (*A* and *B*). *A* is a square long box large enough to permit the lower portion *B* to slide within it and be moved up and down by a key working in slots on the outer portion of the foot-piece at *C*. The lower portion for a child twelve years of age should be one inch wide for that part entering the box, and from this point should gradually slope down to the foot-piece to half an inch or an inch. Attached to the upper portion (*A*) and sliding in a collar around it is a U-shaped bar of steel (*D*): when this is applied it is placed a short distance above the knee, and further fortified by a strap *H* (Fig. 14), to prevent any anterior, posterior, or lateral movement of the limb. There is also another strap just above the ankle (*I*, Fig. 14), further to limit motion; the thickness of the lower bar is about a quarter of an inch, except near the foot-piece, where it is considerably under, as in Fig. 13. The upper portion of the upright (*A*) is fastened to the hip-band (*F*, Fig. 14) by a bolt whose head is sunk; the long upright arm can be placed at any angle of flexion and then fixed by tightening the nut. The bolt passes through a square hole at *M* (Fig. 13). Fig. 14 is a lateral view of the splint. Two straps are secured to the foot-piece *L*, one on each side, to which the extension-plasters are fastened by buckles. A shoulder-strap (*J*) is provided, which passes over the opposite shoulder and is fastened to the upright bar by a loop, thus carrying a part of the weight of the instrument. A perineal band (*G*) is fastened to the hip-band and passes under the tuber ischii. The shoe upon the foot of the sound limb is raised from half an inch to two inches. Dr. Judson's instrument is perhaps a little too tight in its lower segment, and the use of two perineal straps and a longer hip-band would add to the stability of the instrument.

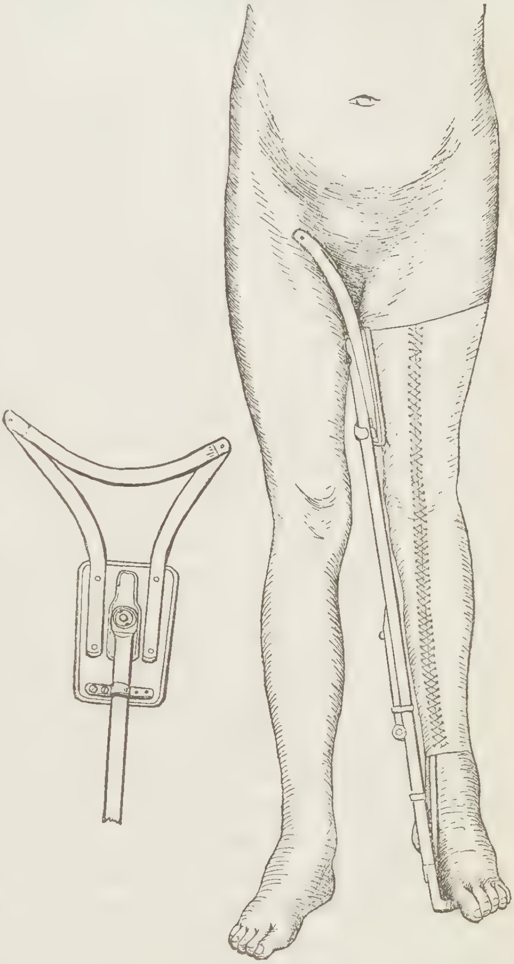
Dr. H. L. Taylor[1] describes an instrument for correcting adduction. "It consists in the shank and side-plate of the long hip-splint ending above in a properly-shaped spreading carrying a perineal strap adjusted to the groin opposite to the adducted thigh. The apparatus is applied to the inside of the adducted limb and fastened by a strap and buckles to adhesive plaster attached to the leg, as in cases of hip-disease. Screwing out the apparatus by the key produces a direct and well-nigh irresistible abducting force, which is easily borne and perfectly under control." Fig. 15 represents such an apparatus. Some splints are provided with an abduction-screw.

There are many modifications of the long splint for the treatment of hip-joint disease made to meet the views of different surgeons, but they do not change the general principle as found in the braces known as Taylor's, Sayre's, or Judson's. Dr. Taylor claims for his splint—and the same claim is made for all splints constructed upon this principle—that it absolutely fixes the joint, that it protects it from all jar and prevents muscular spasm, and that it permits the patient to go about without any injury to the articulation. He makes the following statements: that locomotion with extension after all reflex contractions have been overcome is useful, and, moreover, is a positive advantage, and "a necessity to a perfect articular hygiene," and that "an organ in a certain degree of progressive inflammation presents conditions essentially different from the same organ in the same relative degree of inflammation in the retrogressive stage. Extension can cover, as a means of treatment, but a certain portion of time through which an inflammation of the hip-joint must pass in its several stages. There are positive indications for extension, and there are positive limitations for its use. The limitations are reached at the point when the muscles have become soft and compressible and interstitial movements have become completely retrogressive."[1]

---

[1] New York Medical Journal, 1887, No. 19.

FIG. 15.



Taylor's abduction splint.

We think that these views are too radical, and that the premises are not exactly correct. In the first place, perfect *continuous* extension cannot be kept up, from the very nature of the tissues we have to do with: adhesive plaster will stretch, and the skin will relax, no matter how firmly the splint may have been applied, or how much extending force has been put on by means of the key and ratchet. After the patient has been about for some time the straps at the foot will be found loose; in other words, the extending force has diminished, and continuous extension has not been obtained. Even when the child is in bed with the splint on, the same condition will be found in time,—namely, that the maximum extension cannot be maintained.

---

[1] Boston Medical and Surgical Journal, March 6, 1879, p. 318.

Motion in an inflamed joint, or even in one where the reparative process is well advanced, can do nothing but harm, and is too dangerous a procedure to be thought of. The reliable signs of a cure in hip-joint disease are the disappearance of muscular spasm and the return of the muscles to a soft condition; and until these have occurred the joint must be looked upon as diseased, and absolute rest is a necessity.

In regard to the amount of fixation obtained by this form of splint, the experiments of Dr. R. W. Lovett, of Boston, are interesting.[1] In demonstrating the amount of motion that takes place at the hip-joint in the healthy limb, it was found that with a Taylor splint with one perineal band applied with an extending force of three and a half pounds the thigh moved on the pelvis through an arc of thirty-five degrees in walking; with eight pounds, which could be endured only for a few minutes, there was movement over an arc of fifteen degrees. With two perineal bands better fixation was obtained, though this was not because of the amount of traction, but seemed to be due to the rigid band holding the pelvis and the long leg-shaft holding the leg. Dr. Lovett's deductions from the above are as follows: "That traction in itself furnishes very incomplete fixation, and cannot be regarded as in itself a means of fixing a diseased hip-joint in the treatment of hip-disease; and that a Taylor hip-splint with a rigid pelvic band and two perineal straps furnishes much more complete fixation to the joint than the newer form of the splint with only one perineal strap."

On the other hand, with a diseased joint the tendency is towards fixation on account of the disease itself. In a child with much hip-trouble there will often be found no motion at the articulation, the thigh and the pelvis moving together, or, if there is any motion, it is towards further flexion. The action of an extension-splint passing below the foot and applied in the usual way during locomotion would be to prevent any jarring of the joint by transferring the weight from the foot to the perineum, and by extension to control muscular spasm, and in such a case a movable joint between the pelvic band and the leg-piece is of no use, except to adjust the instrument in the line of the deformed limb (flexion). It would appear, then, that the action of the hip-splint is mainly to prevent excessive joint-pressure, that muscular rigidity has much to do with preventing motion in the joint, and that the splint acts more as a splint than as an extension-apparatus.

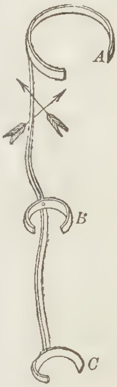
That the hip-splint if carefully applied and watched does act so as to relax the rigid muscles is a fact demonstrated by every-day experience; but that it so acts by reason of the amount of extending force exerted by lengthening the brace is doubtful. The amount of extension represented in pounds that a child can bear is not great enough to antagonize the muscles. Dr. Lovett places the amount of power that a child can endure at less than eight pounds, but a hip-splint cannot be made to keep up its maximum power unless it is elongated every hour or so, and this is seldom done. Continuous extension does relieve muscular spasm. What, then, is the therapeutic action of the hip-splint? It would seem (1st) to protect the joint from jars, (2d) to aid in fixing the joint, and (3d), by fixing the joint and by some traction, to prevent muscular spasm.

---

[1] New York Medical Journal, February 9, 1889, p. 148.

Dr. Thomas, of Liverpool, has devised a splint which is almost universally used in England, which aims to obtain better fixation of the joint. For a child ten years of age the splint is constructed and applied in the following manner. The patient stands upon the sound limb, and rests his diseased limb upon a block or book in order to bring the spine straight. Take a flat piece of malleable iron three-fourths of an inch by three-sixteenths, long enough to extend from the lower angle of the shoulder-blade in a perpendicular line downward over the lumbar region, across the pelvis slightly externally but close to the posterior superior spinous process of the ilium and the prominence of the buttocks, along the course of the sciatic nerve to a point slightly internal to the centre of the calf of the leg. The iron must be moulded to this track, to avoid excoriations. The iron is moulded to the limb in its deformed position. Next measure around the chest a little below the axilla, deducting sufficient to allow the band when bent to be placed easily in position, and have a piece of hoop iron half an inch wide, half an inch thick, and long enough when fitted to the chest to encompass three-fourths of its circumference; this is to be riveted on the upright, at one-third of its length from the end next to the diseased side. Fig. 16, *A*, shows the ring moulded to the outline of the trunk. It is important to give the upper crescent an oval shape, to assist in preventing the instrument from rotating from its position behind the body. Another strap of iron, three-fourths of an inch by one-eighth and in length two-thirds of the circumference of the thigh, is fastened to the upright at a position from one to two inches below the fold of the buttock, as at *B;* then another piece of metal of like strength, equal to one-half the circumference of the leg at the calf, is firmly riveted to the upright at *C*. The instrument should be well padded. The form of the apparatus can be easily changed with hooks. If it should slip around in either direction, a change can be made in the shape of the crescents, and, as the limb gradually assumes a straighter position, the curve in the upright can be changed. The splint is completed by providing a strap with a buckle to secure the chest-piece. After the splint is applied the limb is bound to it with bandages. Figs. 17 and 18 show it in use. A patten about two and a half or three inches high is applied for the shoe of the sound limb.

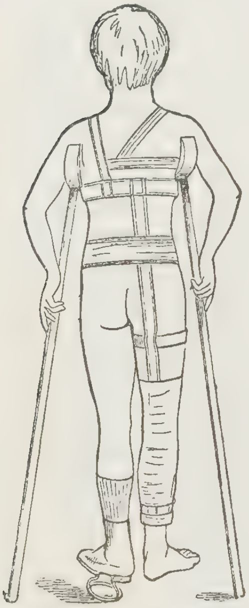
FIG. 16.



Thomas's splint.

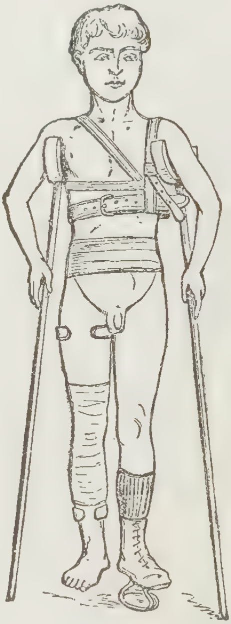
Thomas's splint is based upon a different principle from that known as the American. It depends upon absolute fixation of the thigh on the pelvis and thus securing to the hip-joint perfect rest. But it is a fixation-splint, and in this respect it is an improvement upon the form of splint extending only from the pelvis. Locomotion is not so easy with this splint as with the other. In some respects the principle of Thomas's splint is better than that of the Taylor form, in that there can be no motion at the hip-joint; on the other hand, the American plan affords some extension, while fixation is not so perfect. The former has not the slightest influence in preventing, in the third stage, the head, or what remains of it, from being crowded into the upper portion of the acetabulum, while the latter may do so.

Fig. 17.



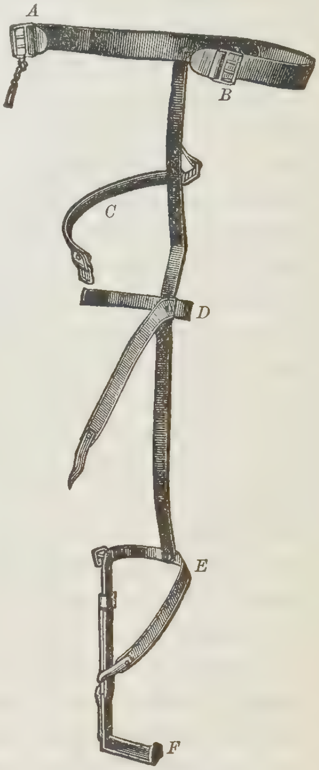
Thomas's splint (back view).

Fig. 18.



Thomas's splint (front view).

Fig. 19.



Dr. Lovett's splint.

Theoretically, a splint combining perfect fixation and perfect extension would meet all objections. Dr. Lovett has acted upon this plan, and has devised an apparatus (Fig. 19) which combines these two points. It is for the left leg. "The chest-piece *A B* is made to open by a hinge at the back, and when closed in place is buckled across the chest. *C* is an arm for the perineal band running in the same place as the perineal arm of the Taylor splint. *D* and *E* are the regulation thigh- and calf-pieces of the original Thomas splint. From the outer end of *E* the foot-piece runs down below the foot, and ends in a ratchet-and-key arrangement for producing extension, in use in the Taylor splint. The splint is applied, the perineal band adjusted, and the traction-bar tightened last of all."

Whether hip-joint disease is treated by extension in bed or by some form of hip-splint, it is a mistake to suppose that as soon as the apparatus or extension is applied all anxiety may be dismissed, and that as long as extension is kept up or the splint used the patient is under appropriate treatment. It is a rule that patients who are kept the most quiet do the best, and that frequent inspection and readjustment of the splint are necessary. Light and sunshine are great therapeutic agents, but when they are obtained at the expense of increased pain and other symptoms of progressive disease it is a question whether we are not doing our patient more harm than good. I do not wish to be misunderstood. If you can keep your patient out of doors in the sunshine and let him have the benefit of good air, it is an incalculable advantage; but if the necessary exercise in obtaining this causes motion in the joint, is there not great risk that more harm than good will be done? Probably the best method of treatment of the early stage of hip-joint disease is to put the patient in bed, apply extension by means of a weight and pulley, and secure absolute rest to the joint by means of a long splint. In the early stage of tubercular osteitis anything that increases irritation and consequently congestion of the parts about the joint favors extension of the trouble and prevents healthy action supplanting the morbid process. Taylor keeps his patients in bed with the splint on for weeks; but continuous extension by means of the weight and pulley fulfils the indications better than a splint. Unless there are contra-indications, such as loss of appetite and failure of the general health, it is better to keep the child in bed for a long time. He grows fat, his appetite keeps good, and he is perfectly contented; and as long as this lasts it is safer than going about with a splint. Later a hip-splint may be used, but with the understanding that the patient should be kept as quiet as possible, the child going about in a carriage. If at any time an exacerbation comes on, the patient should be kept in bed and at absolute rest with a long splint applied, and should not be allowed to get up until all symptoms have disappeared. The advent of an exacerbation means an extension of the disease, and calls for greater rest to the joint. If the child has been up and about, less exercise should be insisted upon. If he has been treated by rest in bed, it is an indication that the disease is progressing notwithstanding our care.

In the second and third stages of hip-joint disease the use of a hip-splint is the best, for the disease has now advanced to the articulation and the joint has become disorganized. If, however, the child is first seen when the disease is at its second or its third stage, treatment by weight and pulley and a long splint is best for some months, and later the application of a hip-splint.

The treatment of hip-disease among the better class and that of the same disease among those in the lower walks of life are different, although the indications are the same. Among the former every suggestion can be carried out, and the child is well fed and well guarded against any injury to the articulation; while among the latter we have to contend against unhealthy surroundings, improper food, want of proper attention, and often ignorance. With this class rest in bed is not to be thought of, and the application of a splint, the use of a high shoe upon the sound limb, and keeping the child out of doors in pleasant weather, is the best that we can do. It is among the children of the poor that we see the disease so frequently running to total destruction of the joint, while among the wealthy we often see the disease checked in its earlier stage. The treatment of hip-disease is summed up in always securing rest to the joint, and in carrying it out the surgeon must adopt those means that, in his judgment, will best fulfil this indication.

In those unfortunate children in whom both joints have become affected, sometimes the disease of the second joint does not appear until it is well advanced in the first, but sometimes both articulations are almost simultaneously affected. In 1878 there was under my care a child five years of age who died early in the course of the disease from uræmia. On post-mortem examination the right hip-joint was found to contain pus; the ligamentum teres was softened, allowing the head of the bone to be dislocated upward and backward. The floor of the acetabulum was diseased over a space about the size of a nickel five-cent piece around the insertion of the ligamentum teres, and was partly necrotic. The cartilage upon the head of the femur was of a yellowish color, and at the point of insertion of the ligamentum teres was diseased. The capsule on its inner surface was thickened and velvety. There was no pus in the left hip-joint; the ligamentum was perfectly healthy. The cartilage upon the head of the femur was white, glistening, and apparently healthy; the acetabulum showed no evidence of disease. There was found a carious spot about the size of a split pea, but of irregular shape, on the upper surface of the head, at a point just below the line of the epiphysial cartilage; the cartilage at this point was destroyed over a small extent. On making a longitudinal section through the head of the femur, that of the right side was perfectly normal; in the left there was a point, corresponding to the carious spot, where there had been a circumscribed osteitis extending inward and upward from the carious point to a spot just behind the epiphysial cartilage. There were other similar but smaller points of the same nature scattered throughout the head.[1]

In this case there was disease about both articulations, and, so far as could be judged, the tubercular deposit occurred in both bones at nearly the same date. In other cases the disease in the first joint may have advanced to total destruction of the articulation before trouble begins in the other.

In some cases of double hip-joint disease there is seen a peculiar deformity known as "cross-legged" or "scissor-leg" deformity. Figs. 20 and 21 represent a case which came under my observation some years ago.[2]

---

[1] Medical Record, November 11, 1879.

[2] Ibid., 1882, vol. xxii. p. 8.

Other cases have been reported.[1] It consists of extension, strong adduction, and rotation outward of both limbs. There are two explanations of this deformity: 1st. There being disease of one hip-joint, the limb on that side is rotated outward and adducted, in order to bring about parallelism of both lower extremities, the pelvis upon the diseased side being raised. Now the other joint becomes diseased, being adducted and rotated outward, and, the pelvis tending to assume a horizontal position, a crossing of the limbs becomes a necessity. 2d. The right limb being rotated outward and held in this position, the knee-joint cannot be used, and is practically ankylosed, so far as locomotion is concerned; this, with contraction of the adductors, throws the limb beyond and to the opposite side of the median line of the body; a similar condition of the left limb, together with the necessity to keep the balance, would cause the peculiar condition and gait. If one strongly rotates outward and adducts both limbs, he must walk cross-legged. But all cases of double hip-joint disease do not show this deformity.

Fig. 20.

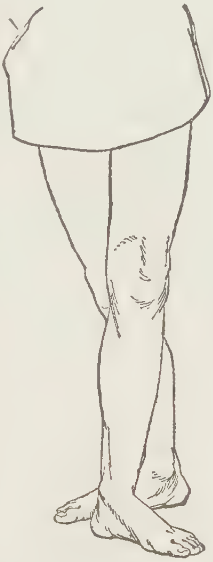


Fig. 21.

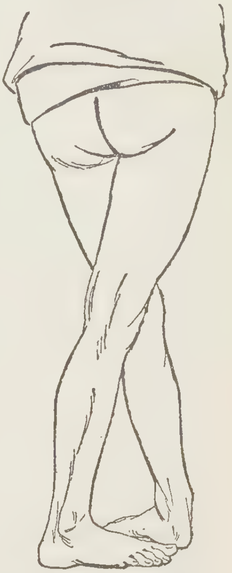

Cross-legged deformity. (Poore.)

The treatment of double hip-disease is double extension, either with weight and pulley or with a double splint. If total destruction of the joint or joints occur, care must be taken that ankylosis does not take place at an angle which will render the limbs useless. In case, however, this should happen, a subtrochanteric osteotomy should be performed and the deformity corrected.

Treatment of Abscess.—It is safe to say that in at least one-half of the cases of hip-joint disease beginning in the bone, abscesses at one time or another present themselves; and their proper management becomes a serious question. Upon this subject there is great difference of opinion,—more than in regard to similar conditions about other articulations. The rules already laid down in regard to the general management of abscesses should be carried out,—namely, as soon as discovered they should be evacuated by a free incision, and the parts disinfected, drained, and dressed antiseptically.

---

[1] Lucas, Transactions of the Clinical Society of London, 1881, vol. xiv. p. 20; Tyson, ibid., p. 186.

Intra-Pelvic Abscesses.—From their position, their danger to important parts, and the liability of the pelvic bones to become extensively diseased, drainage through the joint should be afforded as soon as intra-pelvic abscesses are discovered. Their presence calls for excision of the joint, and a free perforation of the floor of the acetabulum is imperatively demanded, for in no other way can the abscess be reached and drainage provided for.

Results.—The results of mechanical treatment of hip-joint disease differ much. The social position of the patient, as stated before, has great influence upon the result; yet even among the better classes some cases do badly, notwithstanding the attention given the patient. In those cases in which the disease begins in the synovial membrane a cure is effected sooner than in those beginning in the bone. Bone-tuberculosis is, as a rule, slow in its development, and if it pursues a course towards a cure the changes do not take place rapidly. Another element is the duration of the disease and its stage before the child has been placed under treatment. Those cases in which a cure has been effected within six months belong to the synovial variety. In the first stage of articular osteitis, recovery with normal motion is probable; if the disease has advanced to the second stage, a cure with limited motion is possible; but after it has advanced well into the second stage, or has entered the third stage, a joint with any useful motion is an impossibility, and a cure with a stiff joint with the limb in good position is the best result. After the cartilages have been destroyed the articular cavity is obliterated by granulations springing from the denuded surface of the bones, and fibrous or bony ankylosis must result. In these cases there may be some slight movement upon passive motion, but active motion is not attained. In the latter cases if there is any flexion it will increase, because in using the limb the tendency is towards further bending of the thigh upon the pelvis. These are the cases where upon leaving off the splint, although the limb is in a good position, after a time flexion will be found to have increased, as well as lameness in walking. The position in which a limb is ankylosed is not a matter of indifference. If the flexion is great and there is much adduction, the walk will be bad and often a crutch will be required to aid in going about, although the actual shortening may be slight. If the thigh is fixed in a straight line with the long axis of the body, locomotion will be easy, but the patient cannot sit down with any comfort or put on his shoes. Therefore a position which is a compromise between these is the most useful. It has been found that an angle of one hundred and thirty or one hundred and thirty-five degrees with the long axis of the body will give the patient the best use of the limb; all adduction must be removed, but a slight amount of abduction is an advantage, because it causes depression of the pelvis upon the diseased side and compensates for the shortening which is due to actual loss of bone in the joint or arrest of growth in the whole limb secondary to the disease.

The question is often asked whether by early passive motion a movable articulation cannot be obtained, and whether long rest of the joint does not favor ankylosis. Motion in a diseased joint always increases the amount of inflammation, consequently the amount of exudation; rest, upon the other hand, tends to limit disease, and therefore the amount of fibrous tissue. There is no idea more erroneous than that because a joint is kept at rest it will become stiff. No joint ever became ankylosed from merely being at rest; on the contrary, rest is often the only way to prevent ankylosis. Stiffness of an articulation the result of inflammation is due to muscular contraction, or to the products of inflammatory exudation either within or without the joint: therefore the best way is to limit or arrest inflammation, and this is allayed only by keeping the parts quiet.

The deformity after hip-joint disease is often marked, and the question often arises whether an attempt to correct it by forcible movement under ether is permissible. It is a rule to which there should be no exception, that any forcible manipulation of a joint that has been the seat of tubercular disease should never be thought of. The danger of rekindling the disease is great, many joints have been destroyed by such attempts, and often a fatal termination has followed; while, on the other hand, it never does any good. In cases where ankylosis has taken place in an unfavorable position, a subtrochanteric osteotomy is the best and the only justifiable means to correct the deformity. In those cases in which there is limited motion yet the limb is in a vicious position, extension as in the early stage of hip-joint disease may be tried, and then a splint used; but in my experience the result has been disappointing, the deformity after a time returning, the difficulty being that the muscles shorten again and the bands of adhesion resume their former condition.

Statistics as to the final result of the treatment of hip-joint disease by mechanical means vary. Dr. Taylor[1] makes the following statement: "Leaving out of consideration all cases whose histories subsequently to their treatment are unknown or in doubt, I find that there remain ninety-four private cases of hip-joint disease which were under personal observation and continuous treatment from the time they applied until they died or were cured, and whose present condition is now or was very recently a matter of personal knowledge; for no case whose ultimate fate is not positively known deserves a moment's consideration in any estimate of the probable value of treatment for the hip-joint. Of the ninety-four cases three died,—two of the disease, one was run over and killed. Among them there were twenty-four with suppurating joints and discharging abscesses,—nearly all in that condition when first applying. Of these twenty-four with abscesses, two died, and in five the discharge has not ceased. Deducting these seven, there remain seventeen fully recovered, or seventy per cent. of suppurating cases. Three of the seventeen cases recovered have ankylosis, and fourteen recovered with practicable joints,—the majority with ample, and some with perfect, motion. The ratio of motion to ankylosis in cases recovering after suppuration more or less extensive is as eighty-two to eighteen. In two of these cases still discharging, ankylosis is progressing favorably, and in three there is excellent motion. Except for the slight discharge remaining, these would be among our best cases."

---

[1] Boston Medical and Surgical Journal, March 6, 1879.

Dr. Taylor's statistics, although very flattering, are almost useless, because no distinction is made between disease beginning in the synovial membrane and disease beginning in the bone, and they prove nothing more than that these cases of inflammation about the hip-joint recovered. It would be interesting to know how many cases during the period in which these ninety-four were under treatment passed from under his charge, with their condition and subsequent history; for it is a well-known fact that many cases pass from under the care of a surgeon because they are not doing well or have become dissatisfied, and these are the cases that make up the unfavorable side of statistics.

From the annual reports of the New York Orthopædic Dispensary and Hospital from 1880 to 1889, there were under treatment thirteen hundred and thirty-eight cases of hip-joint disease; of these one thousand and eighty-two were discharged. Of the latter, three hundred and forty-nine were discharged cured,—thirty-two and one-third per cent.; five hundred and three discharged relieved,—forty-six and one-half per cent.; one hundred and ten discharged for neglect,—ten per cent.; ten discharged incurable,—one per cent.; and one hundred and ten died,—ten per cent. The reports do not state how many of these were suppurating cases, nor the nature of the disease. The treatment followed is strictly mechanical; the patients are as well cared for as possible, the method is the best in the way of personal attention, and the support is all that could be desired. The condition of those discharged "relieved" is not stated, but it is fair to assume that the disease was not checked, and that it went on to a natural cure or proved fatal from constitutional causes. It is also reasonable to suppose that many in this class ceased to attend because the disease was getting worse, and, as is always the case among the lower and middle classes, they did not bring their children back because they were not improving. Granting that thirty-three per cent. of these would have been cured, this would have raised the percentage of those cured to about forty-eight per cent.

Looking at these two sets of statistics, there seems to be an irreconcilable difference between them. Dr. Taylor's patients are drawn from the most favorable class, while the others are from the lower walks of life. The former show much better results than can be obtained in the treatment of tubercular disease of the bones, taking the cases as they are met with in general practice; while the latter compose those only who are from the most unfavorable class. Statistics are always misleading unless it is known just what class of cases are included.

When a splint can be left off, and what are the signs of a cure in hip-disease, are important questions. In the first place, all pain must have long ceased. A return of plumpness in the muscles of the limb is a sign of no small import. If abscesses have appeared and sinuses formed, their orifices should be depressed and should be drawn inward by an attachment to the bone. Muscular spasms should have ceased, the muscles themselves, if they are not shortened, should be soft, and the joint-movement should be free in those cases in which ankylosis has not taken place. The splint should not be left off at once. Extension may be first dispensed with at night, and the limb gently exercised; then the splint can be left off for a short time each day, so that the muscles may gradually become strong. Finally, after weeks the patient may be permitted to take moderate exercise, care being taken that the limb does not get tired. Dr. Taylor uses a special splint during this period. Notwithstanding our care, relapses will often occur, due either to a new focus of disease or to some injury to the articulation,—a fall or over-exercise. The return of any fixation or flexion in the joint is a very reliable sign that we have to do with a new accession of disease, and that a return to the former treatment is necessary.

COMPLICATIONS.

There are few complications in hip-joint disease that deserve notice.

True dislocation is rare, yet it is sometimes met with during the first stage or in the beginning of the second, when the ligamentum teres has been destroyed and adduction is present: in these cases the capsule may not be ruptured, as proved by post-mortem examination (p. 1160). What remains of the neck of the bone in advanced stages of the disease may leave the acetabulum and be upon the dorsum of the ilium, and may become ankylosed in this position. Gibney has reported two cases, one in which a true dislocation occurred in the first stage. Marsh also mentions a case in which the head of the bone left the cavity of the acetabulum before any diminution of its size or change in its shape had taken place. In these cases, when it has once occurred it is liable to be again displaced. Marsh thinks that dislocation is more liable to occur in acute synovitis; but in the case mentioned above the post-mortem examination showed the absence of any synovitis. Whenever the accident has happened, the dislocation should be reduced at once under ether, and extension applied so as to prevent its occurrence, the treatment being kept up as though it had not occurred. The accident does not seem to have any influence upon the course of the disease.

Perforation of the gut or of the bladder by an abscess is a serious complication. The only case that has come under my observation is the following:

A boy three years of age with disease of the hip-joint came under my care. At the time of admission an abscess had formed and pointed above the joint. He was at the seaside at the time. He had experienced for some time much pain upon any movement of his bowels or in passing water; his bowels were constipated. In November, 1886, he was placed under ether and the abscess opened. The ilium as well as the head of the femur was found to be greatly diseased, the acetabulum was perforated, and a large collection of pus was present in the pelvic cavity. The head and neck of the bone were removed, and the opening through the acetabulum was enlarged so as to afford drainage to the pelvic abscess. The wound healed well, except a good-sized sinus which formed a direct communication with the pelvis. In December fæces of good shape and consistency were found on the dressing after each movement of the bowels; at this time the discharge of pus was slight. In January the child was again placed under ether for examination. There was found a large cavity formed apparently by the abscess forcing the pelvic fascia inward; its boundaries could not be made out with the finger, but the bladder could be distinctly felt. No fæcal accumulation could be discovered, nor on washing out the cavity could any be found in the overflow. Apparently no water passed into the rectum, nor from the rectum into the abscess-cavity, but water passed freely into the bladder and out through the urethra. The patient was returned to bed and serious symptoms were looked for; but there was nothing beyond a temporary elevation of temperature to 103° F. for a few days; there was no cystitis, and from that date no fæces were discovered on the dressings, but urine passed from the wound and saturated the dressing. The patient still passed some water through his urethra, but the greater portion through the wound. In February an opening was made into the bladder, the same as for the median operation for stone, in order to drain the bladder and thus prevent any accumulation of urine, in the hope that the opening into that viscus would close; a rubber tube was inserted. Gradually it ceased to flow from the wound in the hip, and by October the sinus in the hip had closed, also the perineal opening. Since then the child has been well.

Marsh, Wright, and others have mentioned the presence of fæces on the dressings.

Amyloid Degeneration.—Of all complications of hip-joint disease this is one of the most serious. It is usually to be suspected when suppuration has been profuse and the patient has a white, waxy look, and it is one of the most common causes of a fatal termination. But profuse and long-continued suppuration alone is not invariably followed by this change in the liver and other abdominal organs. We often see patients die from exhaustion from profuse suppuration, and on post-mortem examination not a trace of amyloid deposit can be found; while, on the other hand, an enlarged liver, albumen in the urine, and other symptoms may be detected soon after suppuration has commenced. So far as my observation has extended, it would seem that a marked hereditary tubercular diathesis is a predisposing cause; at least the most marked and early cases of this affection have been met with in the offspring of tubercular parents. These children usually die from dropsy and uræmia. When once this change has set in, the only chance of delaying its course is to limit suppuration. That it is not necessarily a fatal complication is proved by a case under my care in 1876. The boy had extensive disease of the hip; there were numerous sinuses about the joint, which constantly discharged unhealthy pus. The disease had existed for four years. The thigh was flexed upon the abdomen and strongly adducted. The liver and spleen were much enlarged; the urine was albuminous; the boy was pale and waxy-looking. In the spring of 1876 the joint was excised; the head was found loose in the acetabulum, and the upper portion of the shaft much diseased. From the date of the operation the boy began to improve, and in December was discharged, with a high shoe and a shortening of four inches, due partly to the amount of bone removed, but chiefly to arrest of growth in the limb. In 1881 he was re-examined; no symptoms of any enlargement of the liver could be found, and the urine was free from albumen. He was earning his living as a plumber. In 1888 I heard of him, and his health was then good.

On the other hand, we not infrequently see patients who have recovered from hip-disease die from the effects of amyloid degeneration which began during the suppurative stage of the joint-trouble. Mr. Barwell mentions the case of a girl seven years of age with amyloid disease, where excision had failed to limit the suppuration. The liver filled the whole right side of the abdomen; the limb was amputated, and the wound healed without suppuration; the liver and spleen very rapidly diminished in size; the albuminuria ceased. Eight years later the girl was fat and healthy. It would seem that the only chance for a patient with amyloid disease is to stop the formation of pus as soon as possible.

General tuberculosis is not a common complication, but tubercular meningitis is. The latter may come during any period of the joint-affection. Marsh states that it is more common in the suppurative stage. But the few cases that have fallen under my observation have been in the early stage of the joint-affection, before pus had been detected. The disease presents various modes in its development, sometimes giving but slight warning until convulsions appear, or it may follow the course so frequently seen in tubercular disease of the brain. It is, unfortunately, a fatal disease, and all that can be done is to relieve the pain and control the convulsions.

Hemorrhage has been met with during the stage of suppuration, from perforation of vessels of varying size.

Growers mentions a neuritis from contiguity of tissues, and Donaldson[1] reports a case of peripheral neuritis and epilepsy occurring in a patient affected with suppurative disease of the hip-joint. But the connection between the neuritis and epilepsy and the hip-joint disease is questionable.

OPERATION UPON THE HIP-JOINT.

There is much difference of opinion among surgeons in regard to operating upon the hip-joint when diseased. Some state that in a large experience they have never found a case so desperate that excision, in their judgment, was called for, while others advocate an operation as soon as an abscess is discovered. That both are honest in their opinions there can be no doubt, yet it seems hard to reconcile these two statements. Perhaps a partial explanation may be found in the class of cases falling under the observation of different surgeons. Those whose practice is entirely among the wealthy do not so often see the disease in its worse forms as those engaged in hospital practice. Statistics of twenty years ago should not be quoted, as improved ways of treatment and operation have placed both methods upon entirely different grounds. The danger to life in operating upon large joints has been so much diminished that a fatal termination from the operation itself is the exception. Large joints are opened, their contents scraped out, or the ends of the bones removed, with scarcely any elevation of temperature following, and but little shock. On the other hand, the methods of treatment by extension or splints have so much improved that as many cases do not run to total destruction of the joint as in former years, and the resort to radical measures is not so often called for. Besides, the pathology of articular inflammation is better understood. For these reasons the question of excision rests upon different grounds from those upon which it rested formerly.

---

[1] British Medical Journal, 1888, vol. i. p. 1003.

A clear distinction should be made between cases occurring in private practice, among those who realize the danger of articular inflammation and are able and willing to carry out to its fullest extent the instructions of the surgeon, and those who belong to the lower walks of life, who often have neither the intelligence nor the time to carry out the necessary treatment, and who live in crowded dwellings contaminated with foul air and cannot procure the proper food so absolutely necessary to combat successfully the constitutional vices to which the disease is due. Among those who draw their experience from these two classes some difference of opinion might be expected; yet I think that the difference is too great, and that there is a middle ground upon which both should meet. There are some cases of hip-joint disease that do well—that is, so far as life is concerned—no matter what treatment is adopted, even when the expectant plan is followed, which is really no local treatment; other cases do badly under the best of management; some cases pursue an almost malignant course, when the only chance to save life is in the total removal of the limb.

The result of excision of the hip-joint renders the patient more or less a cripple for life: the cases that recover with slight shortening are too few to hold out any expectation that they will ever form the rule. So far as the limb is concerned, the best result after an excision will not compare in usefulness to a limb ankylosed at a favorable angle. The question of excision, then, rests upon other grounds than comparative usefulness. We must admit that, notwithstanding the success of the operation, the patient has suffered a serious mutilation. Excision should therefore be reserved for those cases in which no means less severe will accomplish the purpose. Reference to statistics will not afford much aid; they are unsatisfactory and misleading and can be made to prove almost anything. Each case must be judged by itself.

In considering the necessity for excision, the causes of a fatal termination must be taken into account. These are exhaustion, tuberculosis, and amyloid degeneration; and really the question turns upon preventing these diseases.

The mere presence of an abscess is not of itself an indication for excision, for if it is opened and treated antiseptically it may close in a few weeks or months and a good result be eventually obtained. If, however, new collections of pus continue to form, there is every reason to suppose that considerable disease of the bone exists, and in a subject of marked tubercular antecedents it is good practice to open the joint freely and remove the head and neck, curette thoroughly the parts, and wash out the wound with an antiseptic solution, for these are the cases in which amyloid degeneration is prone to show itself, and our only hope for the child is in limiting suppuration by removing the cause. This should not be put off too long: our endeavor must be to anticipate the advent of lardaceous disease and operate before the patient's health has become seriously impaired. The presence of an enlarged liver and of albumen in the urine is an indication rather than a contra-indication for operating.

In cases of profuse or long-continued suppuration in those not of marked tubercular parentage, an operation is called for. A sequestrum in the joint-cavity may be the sole cause of the persistence of suppuration. All cases in which suppuration continues for any length of time, even if it be only from a small sinus, will be benefited by an exploratory operation and scraping the fistulous tract, or the removal of some diseased bone may hasten a cure. On theoretical grounds the presence of tubercular foci calls for excision. I say upon theoretical grounds, because almost all cases of disease of the hip-joint are tubercular in their nature. Yet it is evident that the rule in practice is not and should not be followed. If the presence of tubercle in the bone is as serious as some have claimed, few cases of hip-disease should recover. The question of the duration of the disease is not alone to be considered. If the affection goes on from bad to worse, if we have reason to believe that we have to do with a case in which the tubercular process is advancing, one in which constitutional symptoms are marked and rapid deterioration of health ensues, the indications are to relieve the patient of the source of the trouble as soon as possible.

The presence of an intra-pelvic abscess in connection with hip-disease calls for a removal of the head and neck of the femur and a free opening through the articulation, in order to afford drainage to the pelvic abscess, no matter what the condition of the joint may be.

In cases where the epiphyses have been cast off and the remains of the neck are dislocated, the joint should be opened and the loose epiphyses removed; or where, from the history of the case, such a condition is suspected and there is a sinus, the joint should be opened. I have met with quite a number of this latter class, where, on operation, a sequestrum or loose epiphysis was found.

In children of bad family history, where there has been tubercular disease in both parents' families, or where several brothers or sisters have died from tubercular disease, the question of excision should be considered early, as these are the cases in which a fatal termination is to be looked for. In the last stage of the disease, when the thigh is riddled with sinuses, the bones extensively involved, and the general health seriously affected, excision may be called for in order to make the last days of the little sufferer more comfortable. In private practice excision of the hip is rarely demanded; yet there is no question that a more frequent resort to it would be a gain.

Where an acute condition has supervened on a more chronic state of suppuration, where purulent discharge becomes abundant, and where marked fever and increased weakness supervene, excision is proper.

A persistent elevation of temperature calls for an explorative operation, and may demand a removal of the head and neck of the femur.

Scraping out the joint with a Volkmann's spoon is often followed by good results: only diseased and softened tissue should be removed.

In the early stage of osteitis Macnamara advocates exposing the bone over the great trochanter and with a large drill or a small trephine making a free opening through the trochanter into the neck and, as he believes, into the head of the femur. In one case a small quantity of pus was at once evacuated. The limb was fixed on a splint and the wound dressed antiseptically. There was no elevation of temperature, and from that time the patient lost all pain. The wound over the trochanter healed within a fortnight. Two months later the joint was practically ankylosed, but otherwise the child had good use of the limb. Six years later the limb was found perfectly sound, the patient healthy and able to stand upon the limb all day. Mr. Macnamara's idea is "that by opening the soft vascular tissue in which tubercle is forming, and then establishing efficient drainage, a more healthy action may be established in the parts."[1] Wright[2] mentions having tried this operation in a few cases, and speaks well of it.

Noble Smith[3] has resorted to this method, and states that he has "met with most satisfactory results from piercing the trochanter with one-tenth of an inch and one-eighth of an inch drills, two openings made at about an inch and a half apart being followed by rapid cessation of pain (upon slight movements), heat, and swelling." His method is as follows. A puncture is made with a scalpel over the trochanter to the bone, the periosteum is divided for one-third or one-half inch, the bone is drilled to the depth of half an inch or more, and the parts are syringed out with a solution of carbolic acid, one to forty. I have tried this operation in three cases, and can speak well of it. It certainly stops the spasmodic contractions of the muscles and relieves pain at once. But sufficient time has not elapsed since the operation to allow of our speaking definitely as to its influence on the course of the disease.

In opening an abscess it is always well to examine the joint: this is already disorganized, and no harm can come from such a procedure; besides, it affords a ready way for drainage of the articular cavity.

The views of operating surgeons differ in regard to the advantage of excision of the hip-joint. Bryant states that if dead bone can be made out to exist in suppurating hip-disease there can be no question about the propriety—nay, the necessity—of its removal, and, as it is generally in or about the head and neck of the femur, it seems tolerably certain that the best practice lies in excision of the head. An operation undertaken upon the hip-joint under these circumstances is scarcely any more severe than an operation for necrosed bone, and in all probability is not more dangerous.

[2] Hip-Disease in Children, p. 109.

[3] Lancet, 1889, vol. i. p. 322.

Clowell[1] says "that in hospital cases it should be performed as soon as there is distinct grating in the joint, accompanied by pains, profuse suppuration, or failure of health, and that it should be performed without loss of time as soon as these conditions are recognized."

Wright (*op. cit.*) considers that in hospital cases nothing short of excision can prevent the ultimate progress of the disease and, too often, the gradual exhaustion of the patient from pain and discharge; also that "a knee-joint in which there is suppuration, with caseous masses of bone in the upper end of the tibia or the condyles of the femur, is not looked upon as a condition to be treated by rest, good position, and external applications, but one urgently demanding incision, excision, or amputation."

Barker,[2] in his excellent article on tubercular joint-disease and its treatment by operation, concludes as follows: "I venture to think it would be a wholesome rule that, in cases where general tubercular disease does not contra-indicate it, the infected tissue of the joint should be thoroughly removed as soon as it is suspected that caseation is advancing in it; further, I believe that, until some such rule is adopted as a general guide, improvement in the results of operations on tubercular joints will be slow."

Macnamara[3] says, "If in spite of careful treatment, including efficient drainage and rest, the patient continues to grow worse, grating being detected in the joint, and there is no evidence of lardaceous disease, my advice is, without further delay excise the head and neck of the bone, together with the great trochanter of the femur. . . . It leads to favorable results, provided the operation is not too long delayed."

On the other hand, Mr. Holmes is not an advocate of the operation except in desperate cases. Dr. C. F. Taylor has never met with a case in which it seemed to him called for.

Marsh, although not an advocate of early excision, considers the operation to be called for in the following class of cases. (1) When the whole head of the femur, or what remains of it, has become necrosed and detached, so as to form a loose sequestrum. (2) When, in spite of three or four months' complete rest and free drainage, suppuration remains copious and the general health is giving way; provided, however, that there is no evidence of extensive disease of either the femur or the pelvis and no wide burrowing of matter in the limb. (3) When along with continued suppuration there is so much displacement of the upper end of the femur that the limb cannot be brought into a good position without an operation. Any symptom of amyloid degeneration is, in Marsh's opinion, an additional ground for excision.[1]

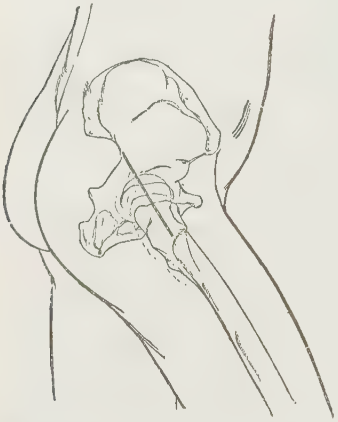
[2] Ibid., 1888, vol. i. p. 1264.

[3] Op. cit., p. 112.

At the New York Orthopædic Dispensary and Hospital, excision is not advised, or at least is not performed.

Operation.—There is no classical operation for excision of the hip-joint. There are many ways of reaching the articulation. A curved incision from the tip around the posterior border of the trochanter affords easy access from behind to the joint and allows of good drainage. Many adopt a straight incision on the outer side, cutting at once down to the bone (Fig. 22). "The patient is placed on the sound side, and the limb flexed; an incision is then made in the long axis of the femur over the outer side of the trochanter major; it should run a little behind the middle, and correspond with a line directed towards the posterior superior spine of the ilium; two-thirds, or nearly, of the length of the wound, which is about four and a half inches long, lies over the ilium above the trochanter, and the remaining third upon the trochanter and femur."[2] But in whatever way the capsule is reached, after being exposed it is opened and the bone examined. If the incision is made directly over the trochanter, the tissues over it are to be raised with a periosteal elevator, so that the head and neck of the femur are easily reached. The old method of turning the end of the bone out through the wound in order more easily to divide it is to be condemned: it disturbs the soft parts more than there is any necessity for. After exposing well the head and neck, the diseased parts may be readily divided with an osteotome, and the end of the bone removed from the acetabulum with a pair of strong forceps. The muscles inserted in the digital fossa, if the trochanter is to be removed, should be separated from the bone.

Fig. 22.



Straight incision over the trochanter in excision of the hip-joint. (MacCormac.)

Having taken away the head and neck, the acetabular portion of the articulation should be examined. Any portion of bone that is loose should be removed; but I have never seen any benefit from gouging away inflamed bone in the pelvis, unless it was circumscribed. If the floor of the acetabulum is perforated, it is well to see that there is a free opening into the pelvis, so that there may be good drainage from that cavity. The upper end of the femur is next to be examined, and if there are any points of disease they should be curetted, or if they are extensive more bone should be taken away. As a rule, in advanced cases the neck and upper part of the femur will be found diseased, and a section just above the trochanter minor will be necessary. With a pair of curved scissors all infiltrated tissue and the remains of the capsule should be removed, in order that the wound may be left as healthy as possible. The periosteum should be separated from the shaft as far down as the point of section, and carefully preserved. Some insist that the trochanter major should always be removed, as its presence is apt to close up the cavity of the acetabulum and prevent drainage of that cavity. If there is extensive disease of the pelvis, it is better to remove it; but if the disease is not marked, and the infiltrated tissues about the joint have been freely removed, there should not be much, if any, purulent discharge. Active hemorrhage is slight: it is not often that it is necessary to apply a ligature, but there is always considerable oozing during the operation, and a free discharge of blood and blood-serum for the twenty-four or forty-eight hours after.

---

[1] Diseases of the Joints.

[2] MacCormac, Surgical Operations, part ii. p. 355.

In some cases the shaft of the femur will be found to be thinned, of a dark color, the periosteum easily detached, and the cavity of the bone filled with a dark yellowish-red material. In such cases further section may be made, but only to find the same diseased state. If this condition is left, a cure is very remote: some cases have made a good recovery, but they are the exception and not the rule; the end of the bone will crumble away, granulation protrudes from the cut end, sinuses about the hip will continue, and, later, amyloid degeneration of the abdominal viscera will be found.

The best course to pursue in this complication is either to amputate the limb or to clean out the central cavity of the femur. I have frequently performed the latter operation, and always with benefit. In order that the whole medullary cavity may be cleaned out, the shaft of the femur just above the external condyle is exposed and a button of bone about half an inch in diameter removed; a long probe to which is attached a piece of silk ligature, and longer than the length of bone from the point of trephining to the point of section above, is passed through the whole length of the medullary cavity of the bone; to the latter a long strip of iodoform gauze is securely fastened and drawn through by means of the ligature silk, and the cavity thoroughly cleaned out. The medullary cavity is then washed out by allowing a stream of mercuric solution (one in one thousand) to run through until it is well cleaned. A short rubber drainage-tube is then inserted into the opening in the bone, the edges of the incision are brought together with catgut, except where the drainage-tube comes out, and over this is placed a small piece of iodoform gauze and then an antiseptic dressing. Nothing more is required. The drainage-tube may be removed in a few days, and the wound soon closes. The cavity in the bone should not be syringed out, but should be left alone.

In the first case in which I adopted this plan, on the third day I attempted to flush out the medullary cavity, on the supposition that further cleansing was necessary. The cavity was found to be filled with dense coagulation, perfectly sweet. Since then I have left the parts alone. In one case some osteitis followed; it was detected three weeks after the operation; the shaft of the femur became enlarged, but no further ill effects followed.

The management of the pelvic bones depends upon the amount of disease: if they are extensively involved, not much good, as a rule, is to be expected from scraping and gouging. So far as my personal experience goes, this disease, if at all marked, is a serious complication, and, although the femoral portion of the operation may do well, the pelvis when carious does not take on a reparative action, no matter how freely the diseased portion may have been removed. Cases where the process is more localized, and where sequestra are found, do better. Hancock and Erichsen, it is true, have removed large portions of the ilium with good result, but the bone was necrotic, not carious. I have removed diseased bone about the rim of the acetabulum, when confined to a small spot, with benefit. If there are any abscesses they should be opened, and their walls thoroughly curetted, disinfected, and drained, if possible not through the joint. During the operation the parts should be frequently flushed out with an antiseptic solution. After cleaning out the wound it should be thoroughly washed with mercuric solution (one in one thousand), and the edges of the incision brought together with wire sutures passed very deep except opposite the acetabulum, and here there should be left a good-sized space, much larger than will take the drainage-tube; the latter should be of good size and pass to the bottom of the cavity; around this should be packed iodoform gauze, and over this an ample dressing of mercuric gauze, the whole being secured by a figure-of-eight bandage.

The reason why it is an advantage to leave so much space about the drainage-tube is that after a time the rubber will get infected and have to be removed, and then the drainage will be insufficient. Again, it is an advantage to have a firm cicatrix above the decapitated shaft, so as to hold it firmly when the limb is used; and, besides, by keeping the wound stuffed it heals well from the bottom and affords a better chance for any necrotic tissue that may have been left to escape. It is possible, in this way, to keep the wound aseptic; at least, my cases have done much better since this plan was adopted than they did when the wounds were more generally closed.

After applying the dressing a long splint extending from the axilla to the ankle is lightly bandaged on, and as soon as the patient has been put in bed extension is applied, the plaster for which is put on before the patient is etherized. A long stocking put on over the bandage affords protection from the blood, etc., during the operation.

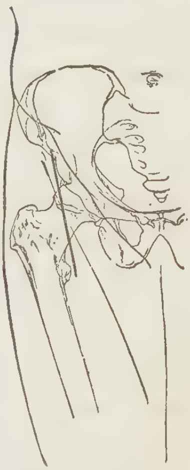
There is usually some shock, but it soon passes off. The use of an opiate is generally required the first night, but after this is not called for. The dressings, as a rule, have to be changed the next day, being filled with bloody serum. The immediate effect of the operation is a marked improvement in the condition of the patient: there is seldom any fever if the wound has not become infected, and there is freedom from pain. The long splint should be retained, and the parts kept as quiet as possible, in order to favor healing of the wound. The patient should not be allowed to sit up.

In some cases after an excision there may be exuberant granulations which show a tendency to break down about the drainage-tube, or there may exist sinuses showing the same character of granulations protruding from their mouths. These are of a tubercular nature, and call for their removal by an exploratory operation, to see if there are any tubercular foci that have been overlooked, and the free use of a Volkmann's spoon. If they are not removed they will further infect the parts, and the disease will not be checked.

Until within the last few years access to the joint has always been obtained by a lateral incision over or near the trochanter major. Lücke, Schede, and Hüter some time ago advocated an incision on the outer side of the crural nerve. Barker[1] has used this method of reaching the articulation, and speaks well of it. The operation is performed in the following manner.

The incision commences on the front of the thigh, half an inch below the anterior superior spinous process of the ilium, and runs downward and a little inward for three inches. As the knife sinks into the limb it passes between the tensor vaginæ femoris and the glutei muscles on the outside of the sartorius and the rectus, until it reaches the neck of the femur. This incision does not divide any muscular fibres, nor any vessels or nerves of the slightest importance. The head and neck are then divided *in situ* and removed with a strong pair of forceps. Fig. 23 shows the line of incision. If there is not found room enough, the incision can be enlarged, care being taken that the Y-shaped ligament is left as far as practicable, the whole operation being done with as little violence to the soft parts as possible. The diseased tissues are then removed with a pair of curved scissors and a Volkmann's spoon.

FIG. 23.



Anterior incision for excision of hip-joint. (MacCormac.)

After removing the head and neck Mr. Barker[2] keeps the wound continually flushed with hot water (105° to 110° F.) which has been previously sterilized and placed in a three-gallon can; this has three taps below, to each of which six or eight feet of india-rubber tubing are attached, and to the latter an instrument consisting of a gouge shaped like a Volkmann's spoon; its handle and shank are hollow, and attached to the end of the handle is the rubber tube.

---

[1] British Medical Journal, 1880, vol. i. p. 16.

[2] Ibid., 1889, vol. i. p. 23.

The instrument is used to flush out the diseased cavity with hot water while the softened bone and tuberculized synovial tissue are being gouged and scraped away. The whole cavity is in this way cleaned, and the diseased tissue, being immediately removed, has no chance to infect the sound tissues; besides, the hot water checks hemorrhage.

After removing all the diseased structures the cavity is dried with carbolized sponges, one or two being left in until all the sutures are in position. These, which are of carbolized gut, should dip deeply and be placed close together. Just before they are tied the sponges are removed, and with them the last trace of moisture. The wound is filled with iodoform emulsion, and the sutures are tied, as much of the emulsion being squeezed out at the last moment as will come away. In most cases no drainage-tube is used. An antiseptic dressing is then applied and firmly held in place by a figure-of-eight bandage.

Mr. Barker claims for this method that primary union is obtained throughout the whole wound. He reports some cases treated after this manner, and up to date there had been no return of disease, with joints slightly movable. The whole operation is based upon the theory that if complete removal of tubercular tissues from the hip-joint is accomplished the resulting wound ought in many instances to heal by first intention throughout. In one case I tried the anterior incision, and found that the joint was easily exposed and plenty of room afforded. The hot water was not used, and, unfortunately, a point in the wound became infected and a tubercular abscess formed.

The result of excision of the hip-joint in general hospital practice has not been so good as that of other joints. It is very difficult to obtain reliable statistics. Patients are sent out before the real result is known, and many operators fail to state just what is meant by cure.

The following are the results in my own hospital practice. Of forty-nine cases, in nine the patients were between three and four years old, in six between four and five, in six between five and six, in eight between six and seven, in six between seven and eight, in six between eight and nine, in four between nine and ten, in two between ten and eleven, one patient was between twelve and thirteen, and one was fourteen years old. Of these, four are still in the hospital, one of whom is well; twenty were discharged cured; eleven were discharged relieved or unimproved; fourteen died. Of those discharged, three are known to be cured, and eight have died. In regard to the terms "cured" and "relieved," by "cured" is meant that the wound is entirely healed, with no sinus and no pain upon motion; by "relieved," that the wound itself has healed, but that one or more sinuses are present, no matter how useful the limb may be. Of those who died while under treatment, eight died from amyloid disease, two from meningitis, one from tuberculosis, one from peritonitis, and two from exhaustion. Of those discharged relieved, one has never been heard from, six died from amyloid disease, and one died from peritonitis. These figures show that twenty-three cases, or fifty per cent., were cured, and that twenty-one cases, or forty-seven per cent., died.

No patient has died from the effects, immediate or remote, of the operation, while, on the other hand, the general condition of those who subsequently died improved for a time: all pain was absent, many of them were able to be about, and were gaining flesh, and suppuration diminished. The cause of a fatal termination was not local, but constitutional; the operation had nothing to do with it. They died not from but in spite of the operation. The date of the fatal termination in these cases varied from a few months to several years; in some cases the patients after the wounds had entirely healed were going about without support. In two cases it will be noted that death was due to peritonitis secondary to amyloid degeneration. The condition of the bones in all the cases operated upon showed that the disease had advanced to the third stage and often well into it, loose bone being in many instances found in the joint. In a few cases the operation consisted only in removing a detached epiphysis.

In regard to the function of the limb: in some cases it was excellent,—lapse of time had not increased the amount of shortening; but in the majority of cases the limb did not grow so fast as the sound one, and a higher shoe had in time to be used. In most cases after excision of the hip, unless there is a very strong cicatrix the upper end of the femur rides up on to the pelvis at every step, due to stretching of the bands which unite the shaft to the ilium; this increases the shortening, and the joint lacks stability. After excision the patient should use a hip-splint for at least a year after getting up, so that these bands may not be called upon to sustain any weight until they have become dense and strong. One of the patients is now twenty-seven years of age, is perfectly healthy, and has good use of his limb; another is twenty-six years of age, is a plumber by trade, and is able to do a good day's work, although he has seven inches shortening, the greater part due to arrest of growth. The following table shows the amount of shortening and its increase in ten cases which have been examined since discharge:

1 patient at time of discharge had 1 inch; 8 years after had 2½ inches.
1 " " " " 1¼ inches; 18 months after had 1¾ inches.
1 " " " " 1½ inches; 6 years after had 2½ inches.
1 " " " " ¾ inch; 18 months after had ¾ inch.
1 " " " " 1½ inches; 1 year after had 1½ inches.
1 " " " " 1 inch; 5 years after had 1½ inches.
1 " " " " 1 inch; 2 years after had 1½ inches.
1 " " " " 1 inch; 18 months after had 1 inch.
1 " " " " ¾ inch; 3 years after had 1½ inches.
1 " " " " 4 inches; 14 years after had 7 inches.

Of fourteen cases in which the amount of shortening at the time of discharge was recorded, it was slight in two, three-fourths of an inch in two, one inch in three, one and a quarter inches in two, one and a half inches in four, and four inches in one.

In a table given by Wright (*op. cit.*), of two thousand four hundred and sixty-one cases of excision, there were one thousand five hundred and sixty-six cures and eight hundred and forty-one deaths; but these statistics are not reliable; they were collected from all sources. A great many of these cases must have been discharged with open sinuses, and many of them eventually died.

The time of operation has a great influence upon the mortality and upon the proportion of successful cases. Those who excise early—as soon as abscess forms—have much better results and fewer fatal cases; but there is no doubt that many of these patients could have been cured without resorting to so radical a method; on the other hand, those who do not excise until the patient's general health has failed and there is extensive disease, operate too late, and consequently have a greater mortality. There is a middle course between these two extremes, which is the safer to follow.

Turning to the valuable reports of a committee of the Clinical Society of London found in the fourteenth volume of the Transactions of the society, and based upon statistics derived from three hundred and eighty-four cases treated without excision, of which two hundred and sixty were suppurating and one hundred and twenty-four non-suppurating cases, the results are as follows. Of two hundred and sixty cases with suppuration, thirty and two-fifths per cent. died from causes connected with the disease, of which nine and one-fifth per cent. died from tubercular affection. The average duration of treatment was two and a half years; the average shortening in thirty-three cases, one inch and three-fifths. The movements were free, limited, or *nil* in the proportion of five, four and a half, and three. Of one hundred and twenty-four cases without suppuration, the total mortality was ten and one-half per cent., and that from tuberculosis was seven per cent. The average duration of treatment in cases that recovered was less than three years.

In Wright's personal statistics, of one hundred cases eighty-five recovered and fifteen died; but on examining his table it is found in the last report that there still existed one or more sinuses in sixty-four cases, so that, strictly speaking, these should not have been reported as cured.

The results of excision are such that it must at present be put down as an operation of necessity, and should be advocated only in those cases where from the family history of the patient or the condition of the parts a cure by mechanical means seems remote. I have an impression, which cannot be proved by statistics, that those who have had tubercular joint-disease are not long-lived,—that they generally die before they reach very far in adult life; and this is strengthened by the fact that the offspring of tubercular parents are of feeble resisting power and die early in life.

DISEASES OF THE KNEE-JOINT.

"Next to the hip-joint the knee is most liable to inflammatory affections in childhood. It is the largest joint in the body, alike in regard to the size of the articular ends of the bones, the extent of its synovial membrane, and the area of its cavity. Any affection of the joint, therefore, especially any acute inflammation, is necessarily on a large scale, and is liable to be attended with a corresponding amount of constitutional disturbance. Owing to the shape of the articular ends of the two bones of which it is mainly formed, and the way in which the shallow facets of the tibia are constructed to slide upon the condyles of the femur, displacement very readily occurs when the joint is in the position of semiflexion, which it at once assumes as a position of greater ease when it is attacked by disease. In this attitude the tibia is in contact with the femur over only a very limited surface, and is easily drawn backward towards the popliteal space by the hamstring muscles. . . . All muscles surrounding the knee are, more than those surrounding any other joint, the hip excepted, liable to be the seat of continuous and severe reflex contractions whenever inflammatory disease is present. The joint is formed by the opposed ends of two long and powerful levers; it is situated in the middle of a bulky limb which contains an elaborate system of powerful muscles, which connect with the trunk by means of a joint that allows motion in every direction; the ends of the femur and tibia which meet at the knee are those in which growth in length of the lower extremity is mainly effected, and any extensive interference with them is liable to be followed by arrested development of the limb."[1]

The knee-joint may be the seat of acute, subacute, or chronic disease, which may involve the bones or the synovial membrane.

SYNOVITIS.

Acute synovitis is not uncommon among children: the exposed situation of the joint and its almost subcutaneous position make it very liable to injury. The cause of acute synovitis may be a sprain, a wrench, a blow, or any injury; it may follow exposure to cold. The seriousness of the case will depend not only upon the amount of violence, but also upon the constitutional predisposition of the child. It is not often that a simple synovitis becomes purulent. If, however, there is a tubercular diathesis, the injury may be the starting-point of tubercular disease of the articulation. Almost every one who has had much to do with joint-disease among children has seen cases in which an acute synovitis coming on after an injury has not responded to treatment as is usually the case, but has passed into a subacute condition, and after a time the joint will convey to the fingers a boggy feel, or the bones develop tenderness in certain localities, and a tubercular disease of the joint be found to exist. Again, an acute synovitis not properly treated may degenerate into a chronic, and the joint finally become stiff. The prognosis in a case of acute synovitis in a healthy child is good in regard both to the integrity of the limb and to life.

---

[1] Marsh, op. cit.

Symptoms.—From the superficial position of the knee, any changes in its shape are readily detected, and therefore the signs of an acute synovitis are easily recognized. They are stiffness, swelling, heat, and pain. Swelling comes on immediately with the access of the inflammation and follows the outline of the synovial cavity; the patella is raised from its normal position in contact with the condyles by the effusion. All the normal depressions about the joint are obliterated, and the articulation has a puffed-out appearance; the skin, unless the inflammation is very acute, is not changed in color, but the joint feels hotter than the sound one. There is pain upon motion. If the inflammation is more acute, the skin may become red or even œdematous, the leg becomes flexed upon the thigh, that being the most comfortable position for it to assume, and there is an increase of pain, with considerable constitutional disturbance. Pain, however, varies much: in some cases while the joint is at rest it is only slight, while in others the patient is kept awake by its severity. As a rule, the more acute the disease the greater the pain and the higher the temperature. If the affection is very acute, there may be some muscular atrophy, and this may give the impression that the capsule is more distended than it really is. The contents of the joint in acute synovitis will show only a turbid albuminoid fluid, more limpid than the natural secretion of the joint: its turbidity varies; in the more acute cases it may be opaline; in cases after severe injury it may be, and often is, stained with blood.

Treatment.—The cardinal point in the treatment of synovitis of the knee, as of all other joints, is absolute rest to the articulation, and this must be rigidly carried out. The child should be confined to the bed, and the whole limb fixed by means of a splint extending from above the hip to below the foot, so as to prevent all motion in the hip, knee, and ankle; besides, there should be a posterior splint applied to prevent any flexion at the knee. Should there be much flexion at the knee, it is better to give ether and place the limb in a straight position; this can be done without any danger, for as soon as the muscles are relaxed this can be accomplished without the use of any force, or the same end may be attained by extension applied to the leg. If the joint is left flexed, a posterior dislocation may take place.

After securing absolute rest, cold should be applied to the joint, by means either of an ice-bag with several layers of flannel interposed between the bag and the joint, or of cold evaporating lotion; lead-and-opium wash is often useful. Some writers advocate the use of leeches, but they are apt to frighten children, and, besides, the disease can be controlled as well without their use. If the pain is marked, opium should be given and its effects carefully watched. The child will experience most comfort from placing the whole limb upon a pillow, support being given to the thigh and leg. When the tension is very great and the pain severe, relief may be obtained by puncturing the joint and removing some of the effusion; this should be done with great care and by means of an aseptic needle. If there is much spasm of muscle, extension should be used, the force being applied in the long axis of the leg. Treated in this way the inflammation will be subdued; but the patient should not be allowed to use the limb for some time, a posterior splint being kept on.

Subacute or chronic synovitis sometimes persists after an acute attack; when this exists a rubber bandage may be applied, and the joint kept at rest. Blisters have also been advocated, and often do good. But our main reliance must be upon rest and fixation, or a Thomas splint may be applied and the patient be allowed to go about; for a description of this splint reference is made to another portion of this article.

Sometimes an acute synovitis will become purulent,—that is, effusion will gradually assume a purulent character without much increase in the constitutional symptoms. When this occurs the joint may be washed out with a mercuric solution through two canulas, one placed on either side of the joint, and the solution allowed to run through until it comes out clear.

Suppurative Synovitis may follow a blow or other injury, but is most generally met with after wounds of the articulation from which the joint has become infected; it may be caused by the spread of inflammation from surrounding parts, as an abscess bursting into the synovial cavity.

The symptoms, both general and local, of a purulent synovitis are marked. It is often ushered in by a marked chill, high temperature, and notable constitutional disturbances. Swelling and pain in the joint are marked, so that the least jar of the bed or room will aggravate the sufferings. The skin soon becomes œdematous and red, and often the seat of phlegmonous inflammation. If there is an external wound, it will look angry and pus will flow from it. If there is any doubt as to the nature of the effusion, a hypodermic needle will settle the question.

If pus is found in the joint, only one course is to be pursued: the articular cavity must be freely opened—under antiseptic precautions—on both sides, and the cavity washed out with mercuric solution, one in two thousand or one in fifteen hundred, and finally with one in one thousand. There are in the joint three spaces which should be thoroughly drained,—the subcrural pouch above the patella, the space under the ligamentum patellæ, and the posterior aspect of the joint. Into these short rubber drainage-tubes should be passed, so as to be just within the synovial cavity, which should then have a final flushing through these drainage-tubes. The incision should then be closed except where the tubes pass out, the part surrounded with an ample antiseptic dressing, and the limb thoroughly immobilized. The dressings will probably have to be changed daily and the cavity flushed out.

Under this treatment the temperature will go down, the pain cease, and, as a rule, the articulation be saved. But action must be prompt: every hour of delay after the advent of the disease adds to the danger to life and limb.

Mr. Treves[1] adopted a plan of continuous flushing of the joint with cold water rendered antiseptic with various substances; the irrigation was done through two tubes, one on each side of the joint, into one of which a continuous flow of water was sent to be discharged through the other. This was kept up day and night for one month. The patient "had a very high grade of inflammation in and about the joint; the whole limb was œdematous." The effect of the irrigation was very marked. At once the patient was free from all pain, the tongue, which had been dry, became moist, and he recovered with a normal degree of motion.

In purulent synovitis of a not very intense type, good results have been obtained by puncturing the joint with two good-sized trocars, one on each side, and washing out the joint by allowing a stream of mercuric solution (one in two thousand) to flow through the joint. In one case I tried this method, with very satisfactory result. Carbolic-acid solutions, except when very weak, have not acted well in my hands, as they are apt to coagulate the fibrin and cause thickening of the capsule.

When there is an extensive wound into the joint, the articulation may still be saved by careful antiseptic treatment; but if inflammation has gone on to destruction of the joint, the most favorable result is an ankylosed limb. In these acute inflammations one of the great dangers is that the tibia may become dislocated backward, and to prevent this the limb should be kept in a straight position. Of course the strength of the patient must be kept up by tonics, plenty of food, stimulants, and opium to relieve pain. If these means fail to limit the inflammation, nothing will save the patient's life but amputation.

TUBERCULAR DISEASE OF THE KNEE-JOINT.

The synovial membrane is more frequently affected with tubercular disease than any other articulation. Its exciting cause may be an injury of some kind, or it may be impossible to connect it with any traumatism; it may develop after an acute synovitis, or may come on so quietly that its exact advent cannot be determined; but, whatever its exciting cause, there is always a tubercular diathesis back of it, and without this strumous disease never occurs.

Symptoms are often insidious: it may come on spontaneously, with stiffness as an early symptom; there may be an absence of pain, yet the patient will limp from inability to extend the leg fully upon the thigh,—and this is an important indication of disease. With this stiffness there is always swelling, for to this latter is the stiffness due. The disease may begin with obscure pains and a feeling of weakness in the joint, with which there is stiffness, and a slight limp may continue for some time without any other symptom to attract attention, although a careful examination of the joint will at this time detect some thickening of the synovial membrane and slight swelling of the joint-tissues.

---

[1] British Medical Journal, 1888, vol. ii. p. 8.

In other cases the swelling will come on without the least pain either in walking or upon pressure. The swelling in these cases is peculiar and characteristic: at first it may have the form of the synovial sac, and in this stage fluctuation in some cases may be detected; soon, however, it changes to one of a soft semi-solid nature, conveying to the touch a boggy feel, as though the joint were filled with a gelatinous material. Barwell states that in those cases in which there is fluid at first the joint tumefaction may be only temporary, to be soon followed by the characteristic doughy swelling of tubercular disease of the synovial membrane. When the disease pursues its usual course, the swelling first shows itself at the side of the patélla and then extends to the whole joint, so that all the normal depressions are obliterated and the limb at the knee-joint assumes a rounded or fusiform contour. The skin has a white appearance. Barwell states that the more intense this whiteness the more marked is the tubercular infiltration. The amount of swelling may be determined by comparing the measurements around the two joints.

Marked atrophy soon takes place in the muscles of the thigh and leg, making the diseased joint more prominent than the swelling alone would do. Atrophy is an important symptom, no matter how slight it may be. It is generally present within a few weeks of the commencement of the swelling and persists throughout all phases of the disease. In old cases the bones of the thigh and leg seem covered only with skin and fibrous tissue, so profound has been the muscular wasting. In time the atrophy involves the bones, so that they are much smaller than those of the sound limb.

Sooner or later in those cases that do not receive proper treatment, or in which the progress of the disease has not been stayed, the joint becomes completely disorganized; the leg becomes flexed upon the thigh, often to a marked degree; the tibia is liable to undergo displacement in the direction of a rotation outward, and a sliding backward of the head of the bone upon the condyles of the femur, and also a sliding outward. As the disease advances, the joint-cavity becomes filled with a pinkish-gray pulpy mass; the synovial membrane is greatly thickened, the ligaments are softened, the cartilage is eroded, and finally the bones become involved in the disease. Abscesses form in this granulation-tissue within the joint, and the pus slowly perforates the capsule; the skin becomes red and tender, then ulcerates over a small extent of surface, and allows the thin, unhealthy pus to escape. Long before this has taken place every tissue in the joint-structure has become infiltrated with this gelatinous material.

One of the most unfortunate complications is the dislocation of the tibia backward, due in part to the flexion of the leg and to the contraction of the muscles on the posterior aspect of the thigh, and in part to the destruction or softening of the lateral ligaments of the joint. The appearance of the limb after this has taken place changes entirely : the swelling disappears to a certain extent, and the end of the femur stands out over the head of the tibia. This displacement of the tibia may take place with or without the occurrence of abscesses, and the bone may become ankylosed in this position.

Pain at some time in the course of the disease is marked, even if it is absent in the earlier stage. As the cartilage becomes eroded, there occur frequent painful startings of the limb, similar to those in disease of the hip-joint. There may be, however, a dull aching pain, increased at night, besides the acute suffering due to the crowding together of the inflamed tissue by muscular starting.

Macnamara states that local elevation of temperature affords valuable information as a guide to prognosis. He recommends that the thermometer be used twice a day over the joint and the temperature compared with that of the sound limb. If we find a marked and persistent increase of heat over the affected knee, we may feel sure that changes are going on in the joint which, if not sufficient to excite suppuration, border closely on that stage of the disease.

The course of tubercular disease of the synovial membrane is either towards caseation, towards abscess and inflammation of the whole joint, or towards connective-tissue metamorphosis and cure, depending upon the general health and the treatment of the patient.

TUBERCULAR OSTEITIS of the ends of the bones forming the knee-joint is frequently met with. It may be confined to the end of the femur or tibia, or there may be foci of disease in both bones. These foci may gradually extend by inflammatory and necrotic changes until they reach the joint, or they may become replaced by connective tissue and the joint escape, or, again, these caseous masses may remain quiet for an indefinite time and finally become active and cause destruction of the joint. I have met with these caseous deposits in the head of the tibia or condyles of the femur where no indications of their presence could be obtained by inspection of the articular surface. These tubercular deposits are apt to attack both bones.

The starting-point of a tubercular deposit often is an injury, by which the osseous tissue may be bruised, some blood may be extravasated, or some interference with local nutrition may take place, and thus form a congenial nidus for the tubercle-bacillus. But, whatever may have been the cause of the disease, when once established its symptoms, though at first obscure, in time leave us in no doubt as to the nature of the complaint. The early symptoms of tubercular osteitis are often obscure. There may be some pain, especially at night or after exercise ; it may be an aching or uncomfortable feeling on certain movements, coming some time after an injury, for the development of tubercular disease of the bone is often slow. The course followed by the deposit has much to do with the prominence and rapidity with which marked symptoms show themselves, whether the bone is infiltrated with tubercle, slowly undergoes caseous change, or becomes the seat of connective-tissue changes. In the first variety the joint is soon affected; in the second it may not be affected for months; while in the third it may never show any sign of disease.

The pain may be confined to one of the condyles of the femur or to the head of the tibia, depending upon the bone involved; after a time pain in the bone may be more persistent, but with exacerbations. There is often tenderness upon pressure over a certain point; frequently there will be thickening of the periosteum over this point; if the deposit is situated deep, no thickening, or but slight, may be felt. Gradually the lameness increases and the joint becomes flexed. As the abscess approaches the joint-surface the pain and discomfort increase, as a rule, there are painful startings of the limb at night, and the parts about the articulation appear swollen. Gradually the joint itself becomes enlarged, through effusion which does not disappear after rest; this may continue serous until the abscess opens into the joint, or it may become gradually purulent, or the joint may become the seat of tubercular disease independent of the bone-trouble.

I think that the classical description of the opening of a tubercular abscess of the bone into a joint, followed by acute purulent synovitis, is not in all cases in accordance with clinical experience. I have seen joints which have been invaded by tubercular abscess show but little acute trouble; often we find only the characteristic tubercular granulation which starts from a small opening in the cartilage leading to a tubercular deposit in the end of one of the bones, and the disease follows the course of a tubercular synovitis plus an osteitis, although there is every reason to suppose that the osteitis was primary. The explanation of this may possibly be that a small amount of tubercular material alone entered the articulation and the joint is slowly infected with tubercle. In some cases of disease of the knee-joint rapid purulent infection of the articulation certainly takes place, but it is not the rule. Early in the disease marked atrophy of the muscles of the leg and thigh takes place. In some cases of articular osteitis the tubercular abscess will discharge not into the joint, but into the soft parts outside of the capsule. The symptoms of a tubercular abscess approaching the surface are increased local deep-seated swelling, increased tenderness upon pressure, often accompanied by throbbing pain (the latter may be intermittent), later local redness of the skin, and finally an abscess in the soft parts.

The fact that a tubercular abscess has opened outside of the capsule does not prevent it from making a way for itself also into the joint, especially if the first sinus is small. A time comes in almost all unrelieved cases of bone-tuberculosis near the joint when the articulation becomes completely disorganized, abscesses have formed and opened at different points, the joint is deformed and misshapen, and the patient suffers from the effects of suppuration, long-continued pain, and confinement.

In some cases after the tibia has become dislocated backward, the inflammation will subside, the pain be greatly diminished or entirely cease, and a cure be effected with the limb in a deformed position. This occurrence is more common after non-tubercular epiphysitis than in tuberculosis, yet it has been met with in the latter.

Tubercular disease beginning in the bones about the knee affects the joint secondarily, but the articulation does not escape so often as when the bone-disease is of a non-tubercular nature. The prognosis is, as a rule, good in children of not marked tubercular antecedents. Death from this form of joint-disease is not so common as from similar disease of the hip-joint. With proper treatment many cases do not go on to the formation of abscess, and a cure with some useful motion, even in apparently unpromising cases, is not unusual. After disorganization of the joint a cure with ankylosis is to be expected. My impression is that general tuberculosis is more common with disease of the knee than with that of the hip; at least this has been my experience.

Treatment of tubercular synovitis is absolute rest. If the disease is detected early and absolute rest of the joint obtained, in subjects of fair health a cure may be expected with perfect or slightly-restricted motion.

In order to fix the knee-joint, rest in bed must be insisted upon, with a posterior splint extending from the hip to below the foot, with an upright at a right angle to the leg, so as to prevent all motion at the ankle-joint, or a plaster-of-Paris splint may be applied. Any flexion that may exist must be corrected. It may be done at once under an anæsthetic, or gradually by extension, for, no matter how rigid the joint may be in the earlier stage, as soon as the patient is under an anæsthetic the muscles will relax and the leg can be put in any desired position without the use of the least force. If, however, the muscles on the posterior aspect of the limb have become shortened, and force is used to straighten the leg, there is great danger that the tibia will slip back and a dislocation be produced. If the disease is not very acute, an elastic bandage (rubber) is often of use: the "Empire porous elastic bandage," which consists of an elastic webbing made very loose, is an excellent substitute for the rubber bandage; it does not confine the moisture, and any amount of constriction can be obtained, and it is much more comfortable than the common elastic bandage. The limb should be kept still in the posterior splint and bandaged below the knee.

The use of counter-irritation is well spoken of by many: small fly blisters may be used, or, better still, a Paquelin's cautery applied very lightly while at a white heat. If blisters are used, they should be about one inch square, not kept on too long, and the blebs allowed to dry as soon as possible. If at any time abscesses form, they should be opened at once.

After the more acute symptoms have passed, the use of a Thomas splint affords excellent protection, and with a high shoe the patient may be allowed to go about. The splint is constructed in the following manner (Fig. 24).[1]

"It consists of an upper iron ring (*A*) three-eighths of an inch in thickness. This is well padded. The ring is nearly oval in shape. From its upper and lower portions two iron rods (*B*, *B*) pass down below the foot; the oval ring should join the inner stem, forming an angle of fifty-five degrees, which when correctly padded is reduced to forty-five degrees. This arrangement of the splint will be the most comfortable. On the end of the two iron rods is placed a patten. Across the bars is stretched an apron of leather, to support the limb, and in the leather are two slits for the insertion of the bandage. A patten is also worn under the shoe of the sound limb. A strip passes over the shoulder of the sound side and is attached by a buckle anteriorly and posteriorly to the oval ring."[2] This apparatus can be used without the leather back, the knee being secured in a plaster-of-Paris splint or a posterior splint, and a bandage over all. Fig. 25 shows the splint applied.

FIG. 24.

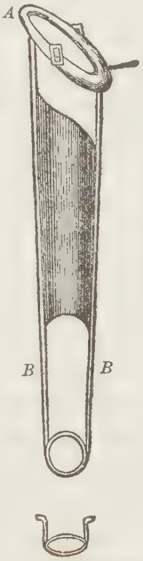


FIG. 25.

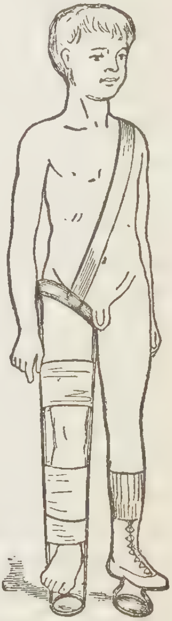

Thomas's splint for knee. (Marsh.)

The splint should be worn for from six months to a year or more, according to the condition of the limb, or until the joint assumes its natural appearance. By this means a posterior dislocation, if not of long duration and if the parts behind the joint have not become too much shortened, may be overcome.

If the joint is much deformed by displacement of the tibia, it may be slowly corrected by gradually changing the angle of the posterior splint. After a dislocation of some duration the muscles in the posterior aspect of the thigh have become shortened and the capsules thickened and shortened, so that even if the tendons are divided the tibia cannot be replaced, on account of the condition of the capsule. Besides, the articular ends of the femur and tibia have become altered in shape, the condyles of the femur being elongated and more conical, and thus overhanging the tibia, so that, if it were possible to bring the articular end of the tibia forward by relaxing the soft parts, the changes in the femur would absolutely prevent the replacement of the tibia being maintained. It is true that splints have been devised which, it is said, will correct this deformity. They are generally constructed with a gutter extending up the thigh and down the leg, with a hinge opposite the joint, and worked with a screw. But the action of these devices is rather to increase than to diminish the amount of deformity.

---

[1] Marsh, p. 440.

[2] Thomas, Diseases of the Hip and Knee and Ankle Joints, p. 98.

Of course the patient should be kept in the best possible condition as to his general health: plenty of food, fresh air, and sunshine are to be desired.

The management of tubercular and that of non-tubercular osteitis are the same. The treatment in the first stage is that of osteitis, and there must be absolute rest of the parts. As said before, tubercular osteitis is often insidious in its beginning; the lack of marked symptoms often misleads one as to the true nature of the complaint, and in many cases treatment is not begun until the disease has made considerable advance. A history of occasional pain and lameness, of pain after exercise, or of stiffness in the morning should always excite suspicion as to the existence of an articular osteitis. In a child of tubercular antecedents any injury to the knee-joint should not be looked upon as a slight affair and of little importance, but longer rest and greater protection to the joint should be insisted upon than in a child of perfectly healthy parentage. For tubercular osteitis there is no better or safer treatment than rest in bed with the joint in a good position and a posterior splint applied. The child may be taken out of doors daily in a carriage, and thus have the advantage of air and sunshine. For those in the lower walks of life, who cannot afford the time and care required to carry out this method, the best that can be done is to apply a Thomas splint and a high shoe on the sound limb, and allow the child to go about. Of course a posterior splint should always be applied. This may consist of a plaster-of-Paris splint about the knee. To apply a posterior splint and then allow the child to go about, using the limb, is no treatment at all. If pain increases and symptoms of an abscess in the bone show themselves, there is no better or safer plan than to cut down upon the tender point, apply a trephine, and clean out the abscess-cavity. We may go even further, and say, if a child has received any injury to the articular end of one of the bones, and after rest for weeks there still continues a tender point over the bone, it is good practice and safe to trephine over this point and allow drainage from the bone. There is no danger from this if properly performed, and we certainly are working in the right direction. I have seen good results from this method of treatment.

OPERATIONS UPON THE KNEE-JOINT: ARTHRECTOMY AND ARTHROTOMY.

Operations upon the knee have gained much in favor since the indications and methods of operation have been better understood. In children they have been condemned by some surgeons because of the shortening that is liable to occur from arrest of growth if the epiphysial cartilages are interfered with. In very young children some operations are questionable. In private practice they are very seldom called for. That a radical operation should not be condemned on account of the shortening, I am satisfied from my own experience; that it should always be resorted to as soon as the joint becomes the seat of an abscess, is bad surgery. What, then, are the indications for opening a knee-joint? Suppuration, either acute or chronic, demands an explorative operation, because, if unrelieved, it will most certainly, sooner or later, destroy the articulation, and by early interference a recovery is generally obtained with more or less useful motion. Chronic suppuration must be due to one of three causes: it is the result either of acute inflammation, of tubercular synovitis, or of a tubercular or non-tubercular abscess of the bone which has opened into the joint. In any of these conditions, if we can remove the cause, a much better result can be obtained by surgical interference than by the expectant treatment. In cases of tubercular osteitis where an apparent cure has taken place, there often remain caseous deposits of varying size which are a constant source of danger to the joint: they may at any time break down and gain access to the joint-cavity. These foci are often met with in cases where after an apparent cure we are called upon to operate to correct a deformity, the patient complaining only of vague pains at times in the bone. There is often also some tenderness on pressure over certain points. Upon section in such cases there will be found in the condyles of the femur or head of the tibia a mass or masses of caseous deposit of varying size, which no treatment other than their removal would get rid of. Children with these deposits never have a useful limb; they are always liable to attacks of pain; and, if unrelieved, joint-trouble will at some time break out again.

In all operations upon joints every precaution should be taken to prevent infection, not only from any disease within the articulation, but also from without. The limb as well as the instruments should be washed and disinfected. There are two operations for disease of the knee-joint, having in view the removal of diseased tissue with preservation of the limb,—arthrectomy and arthrotomy.

Arthrectomy consists in fully exposing the whole of the interior of the knee-joint, and in completely removing the diseased synovial membrane, ligaments, cartilage, and bone, without any formal removal of the articular extremities. In fact, it is a removal of all diseased structure of a joint, and the removal of diseased structure only.[1] It is applicable to most cases of tubercular synovitis where the bones are not greatly diseased; it is not followed by arrest of growth in the limb, because the epiphysial cartilages are not interfered with. A movable articulation is a possibility, depending upon the extent of disease in the joint, but not a probability.

After rendering the limb bloodless, either by an Esmarch bandage or by raising the limb for a minute or so and then applying a constricting band,—the latter being the better and safer method,—the joint may be opened by one of several methods. A curved incision below the patella, as for excision of the knee-joint; a curved incision above the patella, extending from the head of the tibia upon one side to a corresponding point upon the opposite side; and a transpatellar incision, have been advocated. But whatever method of gaining access to the joint is adopted, it should be ample, and if more room is required other incisions should be made, so that every part of the articulation can be easily reached. Some operators advocate a longitudinal incision in addition above the patella, in order to reach the synovial sac under the crureus muscle.[1] Clatton[2] uses "a long curved incision through the extensor tendon just above the patella and prolonged downward on each side of the line of the articulation. The patella is then reflected downward and the whole joint exposed."

---

[1] Wright, Lancet, London, 1888, vol. ii. p. 1086.

In the transpatellar incision the cut is made directly through the middle of the knee-pan; in young children this bone can be cut through with a knife, but in older the saw must be used. An objection has been raised to this method in young children, that the cartilaginous patella is liable to give trouble after suturing. Tilling uses a U-shaped incision, but goes below the tubercle of the tibia and then detaches the latter with a chisel and raises it in the flap. After completing the operation the bone is replaced and secured with a nail in the old position. He does not seem to have derived any great advantage from this method.

There is still another incision used,—namely, a longitudinal one passing through the centre of the patella and splitting the tendon of the quadriceps. In four cases I have used this incision; in two the joint was opened in order to remove enough bone to cause ankylosis, in one the operation was performed to correct a dislocation of the tibia backward, and one was an arthrectomy for tubercular synovitis. In all these cases ample room was obtained, and all parts of the joint could be easily reached. After cleaning out the joint the divided patella was sutured with strong catgut. The wounds united rapidly, and all the cases did well.

Having gained access to the joint, with a pair of curved scissors and forceps every portion of diseased tissue must be removed,—synovial membrane, ligaments, and the semilunar cartilage. Particular attention must be paid to the synovial sac above the patella. It can be easily removed by dissecting off with the scissors between the capsule and the loose cellular tissue surrounding it and the bone and muscles; no difficulty will be found in accomplishing this, even with an incision below the patella, and it must be much easier with an incision above that bone. In this way the sac can be removed in one mass. Simply scraping the diseased tissues with a spoon will not do this: they are infiltrated, and nothing short of a knife or scissors will accomplish the purpose. Having removed all infected soft parts, all diseased points in the bone must be thoroughly curetted, so that every suspicious tissue is completely removed, even if the infected bone extends up to the epiphysial cartilage: all small pits in the cartilage must be gouged out. In cases where the tibia has become dislocated and cannot be brought into position after free tenotomy, sections must be made from the end of the femur and tibia, but for mechanical purposes only.

---

[1] Wright, op. cit.

[2] Lancet, 1888, vol. i. p. 762.

After all diseased tissue has been removed, the parts are to be thoroughly washed out with a mercuric solution (one in one thousand), care being taken that every crevice in the joint is well flushed. After removing the constricting band, all bleeding points are to be ligated. Very hot water should be used in these cases for flushing out, as it prevents oozing. If an Esmarch bandage has been employed there will be considerable oozing, and this should cease before the limb is finally put up. The incisions are then to be carefully brought together with silver wire or catgut. A very important point to be attended to is the drainage: this must be ample; it is far better to have too much than too little. One tube should be brought through the popliteal space, one on each side of the subcrural pouch, and one on each side of the lateral incision. The use of nails or pegs is not required.

The limb should be placed upon a posterior splint and put up in plaster of Paris. Iodoform gauze is placed over the line of incision, and over this an antiseptic dressing. The dressing usually has to be removed the day after the operation, on account of the gauze becoming filled with blood and serum, but the iodoform gauze need not be disturbed. After this, as a rule, there is no necessity for changing the dressing for weeks, or until the drainage-tubes are removed. The best result of an arthrectomy is a stiff joint, and this should be the end in view. A movable articulation is possible, but there is danger that the disease may be rekindled.

Volkmann considers that there should be a certain preparation of the joint before the operation,—that all flexion should be overcome by weight and pulley where it has existed and where it is possible to correct it, all abscesses opened and freely spooned, disinfected, and allowed to heal, and all fungoid masses removed from sinuses. He does not use the bloodless method, believing that the condition of the tissue cannot be so well judged of when blanched, and also that the loss of blood is greater after the use of an Esmarch bandage than without one.

The ultimate result of arthrectomy for tubercular disease of the knee-joint is to a certain extent in doubt, as the operation has not been in practice long enough to form a basis for statistics. Out of fifty-five cases thirty-nine were reported as cured, and the remainder as well at the date of the last report. In five cases a subsequent excision had to be performed, and in one other case it would be necessary. Of the five patients on whom the operation of excision was performed, three subsequently had the limb amputated and recovered. Besides these, in three other cases amputation was performed, four patients died,—three from tuberculosis, one in convulsions,—and three cases were incomplete.

According to Wright (*op. cit.*), in those that do well the common factors seem to be (1) absence or small amount of suppuration, (2) superficial or at least not wide-spread bone-disease, and (3) absence of general tuberculosis. All reporters speak of the tendency of the joint to become more or less flexed unless a posterior splint is used for a long time. What is the real value of the operation further experience and time alone can determine.

The advantages claimed for arthrectomy are that the bones are not interfered with, and shortening does not take place, that erasion is not a bar to future excision, and that the patient is not placed in a worse condition by the operation. It is justifiable at an earlier period of disease than an excision, and is peculiarly applicable to children. On the other hand, it perhaps encourages a too early operation in cases that might be cured by non-operative treatment. The tendency is towards more early interference in joint-surgery, and there is great danger that we may be going too far.

Arthrotomy consists in the removal of all infected tissue, together with a section from the articular ends of both the femur and the tibia, without any reference to whether they are diseased or not, so that the two bony surfaces may be brought into contact and osseous union be obtained. Until within the last few years it has been the only operation for disease of the knee-joint except amputation, and for a long time the question was whether to amputate or to excise. Within the last ten years excision has become not a substitute for amputation, but an operation which may be taken into consideration at an earlier date than an amputation is to be thought of, and which aims to secure to the patient a limb not much shorter than the sound one, but with ankylosis at the knee, and one on which he can walk without any pain and with but a slight limp. It is not often performed for disease among the better class, because the joint-disease seldom advances to a degree that calls for any radical operation. It is confined mainly to those among the lower class in whom the disease has been allowed to advance until the articulation has become completely disorganized, the tibia displaced, and the bones seriously involved, or in whom the joint is filled with granulations, the ligaments destroyed, and the bones involved to a greater extent than can be thoroughly removed by erasion,—in fact, to those cases where disease has begun in the bone, so that nothing short of a complete eradication of the disease will put the parts in such a condition that a cure with a useful limb is possible.

There are two conditions of the knee-joint in which a classical excision is the only remedy: in an old posterior dislocation, owing to the changes that have taken place in the femur and tibia, and the shortening of the soft parts behind the knee, a removal of sections from both bones is absolutely necessary in order to bring the leg in a straight line with the thigh; the other is bony ankylosis in a flexed position.

In children under six years of age excision is not a satisfactory operation: the liability to excessive shortening is great, and the danger from general tubercular infection is greater than in those above that age: at least such has been my experience. There can be no doubt that a short limb with a high shoe is a far more useful member than the best artificial limb that can be obtained. There is no danger of ulceration from pressure, no constant expense for repairs and replacement. The usefulness of a limb after excision with bony union is excellent, and it would seem that the objections raised against the operation as now performed are altogether too strong.

Operation.—The parts should be thoroughly disinfected. The joint may be opened by a U-shaped incision either above or below the patella, or by some operation like the transpatellar method or the longitudinal. It is better not to use an Esmarch bandage: simply raising the limb for a minute or so and then applying a constricting band will render the limb almost bloodless, and there is not the troublesome oozing that follows the use of a rubber band from the foot to the thigh.

Having exposed the joint, the leg should be well flexed, so that the whole articular surface shall be exposed. All diseased tissue is then to be removed thoroughly with scissors or knife; and the synovial sac above the patella must be dissected out. During the operation the parts should be frequently flushed with mercuric solution. The patella should always be removed, for if the disease of the joint is extensive enough to demand an excision the patella is generally found to be diseased. In two cases in which I left it, a subsequent operation had to be performed for its removal, as it had become diseased. Mr. Marsh and others advise its being retained in patients over eight years of age.

Having removed all diseased soft parts and scraped out all sinuses,—or, better, dissected them out,—the ends of the bone are to be removed. This is best done with an amputating saw. The bone must be cut at a right angle to its long axis. The patient lying on his back, an assistant holds the femur perpendicular to the operating-table, being careful not to allow any lateral deviation, and a section is then made. The same plan is adopted in regard to the tibial section. The amount of bone removed should be as small as possible. If not enough has been removed at first either to eliminate the disease or to allow the tibia to be brought forward, further section should be made. If after making a section a caseous mass, an abscess, or necrosed and carious bone is opened into, it can be removed with a spoon, even if a large cavity is left, provided all infected tissue is removed, without any fear of jeopardizing the result of the operation. The amount of curetting that is compatible with a good result is almost unlimited, provided the outer shell of bone is left healthy. If there is necrosed bone extending up the shaft, it can be removed. No more healthy bone should be taken away than is absolutely necessary.

Having seen that the two cut surfaces come together without any tension upon the tissue back of the joint, the constricting band is removed, and any bleeding point ligated. There will be considerable oozing, which may be stopped by the application of hot water. The parts are then to be thoroughly flushed with mercuric solution. After the hemorrhage is stopped, the limb is to be placed upon some form of posterior splint, for the secret of success depends upon absolute fixation of the parts. There are many ways of accomplishing this.

Some use plaster-of-Paris bandage extending from the foot to the groin, with an interval at the point of operation, the two portions of the splint being united with iron bars bent so as to allow of the wound being easily reached. Dr. McBurney applies to the leg and thigh a slight plaster bandage a day or so before the operation, and after it has become dry removes it by cutting it up in the median line. After the operation these leg- and thigh-pieces are slipped on, and the bracket put in position, and over these is applied another plaster bandage. The advantage of this method is that there is a firm basis to apply the iron brackets.

Many use some modification of Watson's splint. For some time I have used a splint made in two parts, one for the leg and one for the thigh, united by two side brackets. It has worked well. After being well padded, the leg portion is secured by a plaster-of-Paris bandage which includes the foot; the upper portion is secured with a coaptation splint placed upon the anterior aspect of the thigh and fastened with two straps and buckles. Do what you will, the upper portion of the splint will get soiled by the discharge running down, and if the thigh is encased in plaster it cannot be cleaned; whereas with the coaptation splint and buckles this can be easily accomplished.

All splints should be padded, and the leg should be somewhat raised, so that the cut surface of the tibia may lie easily against the corresponding surface of the femur. The whole limb is then placed upon an inclined plane, and the parts are brought into coaptation by position, and not by bandaging. Whatever form of splint is used, the foot must be fixed and well raised, so that it shall not sag down and displace the lower fragment. To hold the bones in position many use silver wire or steel nails plated with gold or nickel. The latter should be four and a half inches long and in size corresponding to No. 2 Stubbs's steel gauge; they may be round or square. They should be thoroughly disinfected. Three are generally used, one being driven in from either condyle downward and backward towards the middle of the bone, and one from the middle of the anterior surface of the tibia upward and backward. If they have been properly applied, any movement between the cut surfaces of the bone is impossible. The use of these nails certainly gives additional security to the limb, but it is not a necessity.

It is well to use four drainage-tubes,—two for the sac above the patella, and two at the end of the incision on the side of the limb, so as thoroughly to drain the posterior part of the joint. The incision is brought accurately together with catgut, and over it is placed some iodoform gauze, and then an ample covering of antiseptic gauze bound on tightly.

After the patient has been returned to bed it is well to suspend the whole limb.

The amount of pain after an incision of the knee-joint is not very great if the limb is put up so that there is no uneven pressure and the splint is well padded. Opium will be required the first night, and possibly the second. Theoretically, the temperature should not be elevated if the operation has been done strictly antiseptically; in some cases, however, notwithstanding every precaution, it will be found a little above normal on the following day or the next, but it soon goes down, and if everything goes well there is no further rise. One of the chief causes of trouble and after-pain is an accumulation of blood and serum in the space left by the removal of the synovial sac above the patella. To prevent this, strict attention to the drainage of this sac is required, with care that the tubes do not get constricted by the bandage.

On the day following the operation the dressing will have to be removed, on account of its becoming filled with blood and serum; the iodoform gauze need not be disturbed. After the second dressing it is not often that it has to be removed unless it gets loose. About the third week the nails may be removed; they are usually found loose, and there is no difficulty about it. If abscess has formed, it should be evacuated at once and the parts disinfected. The time necessary for firm union to take place is from eight to twelve weeks.

I have excised seventeen knee-joints, as shown by the table on the following page. Of these cases ten were cured, four died, one was discharged with limb ankylosed but with discharging sinuses, one is incomplete, and in one amputation had to be performed. The cause of death in three was general tuberculosis; one died from heart-failure twenty-four hours after the operation. Of those who were discharged cured, eight are known to be alive and have useful limbs; they have no pain, and walk well without the use of a crutch or cane. Two are known to have died, one from general tuberculosis five years after leaving the hospital, and one from diphtheria eight months after her discharge. In only one case has the union been fibrous, and that was in the child who died from diphtheria, but no flexion had taken place.

The shortening in the case of the boy sixteen years of age, who had been diseased since childhood, was mainly due to arrest of growth; in two cases it amounted to two inches, in two to two and a half, in two to one and a half, and in three to one inch. In regard to the growth of the limb after excision, I have re-examined six patients. In case No. 2 there has been no change for fourteen years; in No. 4 there has been an increase of one and a half inches in seven years; in No. 5, no change in four years; in No. 6, an increase of one-quarter of an inch in six years; in No. 7, an increase of half an inch in four years; and in No. 12, no change in two years.

In one case the limb had to be amputated on account of chronic inflammation in the bone. I am unable to account for this, as it was a case of old dislocation and ankylosis; there was nothing about the bone or the operation to account for the disease in the bone; there were no tubercular foci, the disease being non-tubercular. The fact that during the first night

EXCISION OF THE KNEE.

No.	Name.	Age.	Cause of Operation.	Excised.	Result.	Shortening.	Remarks.
1	A. G.	16	Ankylosed at right angle fourteen years.	June, 1878.	Cured.	4 in.	Has not been heard from since 1880, and then was well.
2	J. S.	14	Ankylosed at right angle, abscess eight years.	Nov., 1879.	Cured.	2 in.	Seen in 1886; good use of limb; does not wear a high shoe.
3	R. P.	3	Tubercular osteitis, abscess.	Dec., 1883.	Relieved.	. . . .	Wound never closed, but patient was still alive in 1888.
4	M. F.	12	Ankylosed at right angle, abscess.	March, 1881.	Relieved.	2 in.	Well in 1889; short two and a half inches.
5	J. R.	10	Ankylosed at right angle, abscess.	Feb., 1882.	Cured.	1½ in.	
6	G. R.	13	Tubercular synovitis, abscess.	May, 1883.	Cured.	2½ in.	Later had curve of spine and tuberculosis; died in 1887.
7	H. S.	7	Tubercular synovitis, abscess.	May, 1882.	Cured.	1½ in.	In 1887, short one and three-quarter inches; had curve of spine before operation.
8	J. H.	4	Tubercular synovitis, abscess.	June, 1883.	Died.	. . . .	Tubercular tumor of brain.
9	L. S.	3	Synovitis and total disorganization.	June, 1883.	Died.	. . . .	March, 1884, curve of spine; wounds closed; union firm.
10	A. J.	13	Synovitis and disorganization.	June, 1885.	Died.	. . . .	General tuberculosis; wound never closed.
11	E. H.	8	Angular deformity, ankylosed.	Nov., 1885.	Died.	. . . .	Amputation for osteo-myelitis.
12	M. M.	14	Angular deformity, diseased four years.	Nov., 1885.	Cured.	. . . .	In 1888 no change in shortening; walks well.
13	L. G.	11	Tubercular osteitis, abscess.	Oct., 1886.	Cured.	. . . .	Died eight months later, of diphtheria; union fibrous.
14	E. B.	8	Infantile paralysis.	Nov., 1886.	Cured.	. . . .	Result good.
15	K. F.	13	Tubercular osteitis.	June, 1888.	Cured.		
16	K. D.	7	Tubercular disease.	May, 1887.	. . . .	. . . .	In hospital.
17	A. H.	7	Tubercular disease.	May, 1887.	Died.	. . . .	Collapsed twenty-four hours after operation.

after the operation the patient tore off the bandage may account for it, as suppuration almost immediately followed.

Case 7 was admitted with tubercular synovitis following a slight injury; the joint presented the characteristic swelling, there was an absence of any pain even on motion, and the skin looked very white; the case was looked upon as being very unpromising. Excision was performed, and all went well for a time, when the spine was discovered to be diseased. The operation-wound closed, and he had good use of his limb. Finally the lungs became diseased, and he died five years after the operation. Case 8 was a child four years of age, with tubercular disease of the synovial membrane and an abscess in the head of the tibia, not surrounded by any sclerosed bone. The wound never did well; disease in the bones continued; after some months brain-symptoms developed, and at post-mortem examination a tubercular tumor of the size of an English walnut was found in the brain. Case 9, a child three years of age, was admitted with tubercular synovitis and osteitis; the parts about the joint were greatly swollen from the middle of the thigh to the middle of the leg; the joint was completely disorganized. Excision was performed; some time later, as suppuration continued, the parts were examined and a sequestrum in the femur was found between the bones; one month later disease of the dorsal vertebræ was discovered, and the patient died. Case 10, a boy of thirteen, had tubercular disease of the synovial membrane of the same character as case 7; excision was performed after abscess had formed; the wound never closed, and he died of pulmonary tuberculosis six months after the operation.

Cases 7, 8, 9, and 10 were unpromising at the time they came under observation, and perhaps belonged to the class in which amputation should have been performed; in this an error may have been made. The question whether infection of the lungs, brain, or vertebræ was caused by manipulation during the operation is difficult to answer, but the possibility of the occurrence of such infection cannot be lost sight of.

Of the death from heart-failure I can offer no explanation. The child was in good condition,—the excision was performed to correct a malposition,—but little blood was lost, and the operation was not a long one. Early in the operation the heart acted badly, and, notwithstanding the free use of hypodermics of digitalis and whiskey, it never regained its force, and the patient died twenty-four hours later from heart-failure. Shock alone did not seem to be the cause.

Quite a number of operators speak of bending of the limb at the point of section some time after the patient was going about. Barwell[1] mentions the case of a boy fourteen years old in whom the union was not bony. Bryant[2] reports the case of a child six years of age on whom three years previous an excision had been performed; the tibia had become bent to an angle of sixty degrees upon the femur; there was no motion at the time of readmission. The malposition was corrected by an osteotomy through the femur. Morgan[1] reports the case of a girl twelve years of age whose knee-joint had been excised one year previous, and in whom the limb had gradually become flexed to a right angle. Baker[2] mentions the case of a boy who when nine years of age had his knee-joint excised. Nine years later the leg was gradually bending; the union seemed firm, yet the limb had bent to an angle of forty-five degrees at the knee. Smith[3] reports the case of a boy eleven years of age in whom excision was followed by bony ankylosis; five years later the limb was bent forward at the point of operation and the tibia and femur were curved. In another boy when five years of age a similar operation had been performed; thirteen years later the limb became bent forward. Howard Marsh[4] mentions a case where at the point of operation the limb became flexed. From an examination of the plate illustrating this, the bending seems to have taken place at the point of operation, the anterior portion of the bony union having become elongated. Phelps[5] reports a case in which the limb was put up in a slightly-flexed position after an excision in a child nine years old; the patient did well, but eight months later the limb became flexed to an angle of forty-five degrees. The child suffered pain at the point of excision during locomotion and on any attempt at straightening the limb. Phelps considered the bending to be due to the action of the hamstring muscles, and advises their resection in all cases, and utilizing the patella to overcome any flexion.

---

[1] Diseases of the Joints, 5th ed., p. 562.

[2] British Medical Journal, 1884, vol. i. p. 1045.

From a review of these cases, there does not seem to be any common cause to account for the bending. In some cases the deformity did not make its appearance for some years after the operation, while in others it came on earlier. It is reasonable to suppose that in Dr. Phelps's case the slightly-flexed position in which the limb was placed might have been an element in causing the deformity. In my own experience no case of bending has been seen, nor do I know of any case in the experience of any one except Dr. Phelps where this accident has occurred. It is known that in some cases after a fracture has finally united bending at the seat of union has taken place, and perhaps the bending at the seat of excision at the knee-joint is due to the same cause. The best safeguard against this accident consists in perfect fixation and coaptation of the bones, and in seeing that the limb be put up in a straight line.

The ultimate use of the limb after excision of the knee-joint is good even when the shortening is excessive. After excision in children the amount of increase in the shortening depends upon the point at which the section of the bones is made,—whether the epiphysial cartilages are left or not. When both epiphysial cartilages are removed in young children, the arrest of growth is great. Holmes[1] mentions the case of a man on whom nineteen years before he had excised the knee-joint for extensive disease accompanied by imperfect ankylosis. The patient was then a child, and both epiphyses were removed. The limb is now seven inches short, yet it is so serviceable that he can walk thirty miles in one day. Lee[2] reports the case of a man on whom twenty years previous, when twelve years of age, he had performed excision. When discharged, the shortening was five inches; now it is nine inches; the patient walks well with a patten on his shoe. It would appear, then, that excessive shortening is no bar to a very useful limb. In only a few of my own cases has a sufficient time elapsed since the operation to afford grounds for reliable statement on this point. In one case, for ten years the patient has had excellent use of the limb, and at one time acted as a line-man for a surveyor and did his work easily. He is now an architect, and goes about buildings under construction without any difficulty. Marsh makes the statement, "The limb after excision, especially in children under nine or ten, is very unsatisfactory; it remains short and becomes in many cases distorted." I know of no case in which a good limb has not been obtained, although the amount of shortening varies. Even in those cases in which it has been excessive a high shoe has permitted the patient to undergo much fatigue without any failure of the limb. Bending does not appear to be common in this country. Perhaps the better food and surroundings which the children of the lower class have here conduce to a better and firmer bony union.

[4] Diseases of the Joints, p. 326.

[5] Medical Record, 1886, vol. xxx. p. 113.

In comparing excision with amputation, there does not seem to be any question that the ultimate result of excision with good union, no matter how great the shortening may be, far exceeds both in usefulness and in comfort the best artificial limb made. The sole of the foot affords the best possible support.

A few cases of motion after excision of the knee-joint have been reported. Bennett[3] reports the case of a girl in whom, two years previous, he had excised the knee-joint. "She can stand upon the limb without support, and can flex it to a right angle." She walked with a little limp. Boutflower[4] mentions a boy seven years of age in whom the knee-joint was excised for deformity; the patella was removed. Nine months later there was motion at the knee-joint over an angle of ninety degrees. It does not appear from these cases that the motion was of any use. From the fact that the patella had been removed in both cases, it is hard to understand how the patient could derive any benefit from this condition.

The accidents that happen in connection with excision of the knee-joint are suppuration, necrosis, caries, and hemorrhage. A limited necrosis is sometimes seen for which no cause can be assigned; it does not necessarily jeopardize the success of the operation, but delays the cure. Hemorrhage of a serious nature has been reported in some cases, from ulceration of the popliteal artery due to pressure or to a spicula of bone. Gangrene of the limb has been met with, from compression of the artery due to stretching of the parts behind the joint. Secondary hemorrhage sometimes occurs.

[3] Ibid., 1884, vol. ii. p. 235.

[4] Ibid., 1884, vol. i. p. 889.

Disease of the bone after excision is met with. It may be due to infection at the time of the operation, or to improper dressing. Movement between the fragments may cause trouble; or a tubercular deposit that has either escaped notice from being situated beyond the point of section, or has not been thoroughly scraped and disinfected, may rekindle the disease. If much suppuration occurs, it is best to open the wound and search for its cause. If it is due to tubercular foci, these may be removed and the wound closed again, after which the case may progress to a favorable termination. If the cut surface of the bone becomes diseased, the parts may be re-excised, but not with much prospect of success, so far as my experience goes.

Amputation for knee-joint disease is not so often performed as formerly, yet in some cases it is the better operation. In cases of injury to the popliteal artery, where the bones are extensively diseased, where the lungs show considerable tubercular deposit, where the joint is enlarged and the skin very white, amputation of the knee-joint may be demanded.

What are the indications demanding excision of the knee-joint?

Ankylosis in a flexed position can be corrected only by an operation, either by removing a wedge-shaped piece of bone, including the ends of the femur and tibia, or by a subcutaneous osteotomy of the femur or of the femur and tibia, one-half of the deformity being corrected by the first section and the rest by the second. This leaves the portion between the two points of operation very prominent, but this in time is somewhat decreased by moulding of the parts. There is, however, danger that the vessels behind the joint may be compressed in correcting the deformity. Old dislocation of the tibia backward can be corrected only by excising the joint.

Excision of the knee-joint for disease is rarely called for among the upper and middle classes, because the disease is seldom allowed to advance to such a state that a cure cannot be obtained without an operation. When suppuration is profuse and long continued, or when in a patient of marked tubercular antecedents the disease does not yield to proper treatment, an operation, even among the better class, should be performed. In cases where the joint has become painlessly enlarged and the skin has an abnormal whiteness, excision is demanded early, and, if the wound does not do well, should be followed by amputation. Where we are satisfied that an abscess in the end of one of the bones has opened into the joint, or has opened outside of the articulation, nothing but the removal of the diseased bone will stop the discharge. Chronic suppuration calls for an exploratory operation, and if the parts are found to be in such a state that a cure by rest is improbable, erasion or excision should be performed. The choice between these two methods depends upon the condition of the bone. The more the disease is confined to the synovial membrane, the better will be the prospect that erasion will eradicate the disease ; on the other hand, the more the bones are involved, the more appropriate is an excision.

In case granulation should appear either in an old sinus or by the side of a drainage-tube, the patient should be placed under ether and the sinus scraped.

HYDRARTHROSIS.

Hydrarthrosis signifies merely fluid in a joint, without conveying any information as to its cause or amount. The word is, however, used to designate a chronic painless or almost painless distention of a joint with synovia, which may only be thinner than normal or may be filled with fibrinous exudation. In some cases the membrane may be thickened, and in older children the synovial fringes may become hypertrophied. The disease is almost always confined to the knee-joint, or at least it is much more commonly met with in that articulation, although it may be found in the shoulder, elbow, and ankle joints. It may be the result of a chronic synovitis or may follow articular rheumatism ; there are some cases in which no cause can be assigned.

The knee-joint is often greatly distended. It is stated that it sometimes contains eight or nine times its normal amount of fluid. In cases of long standing the capsule may become greatly thickened and the ligaments softened and weakened, so that there is considerable lateral movement in the joint, and the articulation gives way when any weight is put on it. The joint in this condition shows little tendency towards recovery.

Treatment.—When the effusion is comparatively recent, rest to the joint by means of a posterior splint and the application of small fly blisters every few days, together with pressure by means of an elastic bandage, may in a few cases effect a cure. In a more advanced condition there is nothing better than injection of the joint after the withdrawal of the fluid, in the following manner.

Having placed the patient under ether and thoroughly disinfected the skin, a small incision is made on the outer aspect of the joint through the skin, and then a good-sized trocar, which has been made perfectly aseptic either by being placed in a solution of carbolic acid (one in forty) or by heat, is plunged into the joint-cavity, and as much of the fluid as possible withdrawn by equable pressure over the joint, so as to prevent the entrance of any air ; the joint is then injected through the canula with a warm solution of carbolic acid (one in sixty) by means of a fountain syringe, until the synovial cavity is well distended ; the fluid is then allowed to flow out, and this is repeated until the fluid runs clear. It will be noticed that the first injection will come out of an opaline color, due to the coagulation of the fibrin ; the second will be less so, and finally it will come out clear or nearly so. During the operation the joint is to be kneaded, so that the fluid shall gain access to the whole cavity. Gerster advises that the first few washings be made with Thiersch's fluid (salicylic acid two parts, boracic acid twelve, hot water one thousand), and the final flushing done with carbolic-acid solution, because the latter hardens the fibrin and renders it difficult for it to pass through the canula. After the operation is completed the canula is withdrawn, and the incision covered with iodoform gauze, and over this a dry sublimate dressing; finally bandages and a posterior splint are applied. The patient should be kept in bed for ten days, when the dressings are removed and the patient is allowed to move the joint in bed, and within a few days to get up.

I have used this method in three cases, and have every reason to be perfectly satisfied with the result. There is, as a rule, no pain after the operation, nor are there any ill effects. Care must be taken that the limb is not kept quiet too long, lest the thickening of the synovial sac be so great as to limit motion.

In case the first operation does not accomplish the purpose, a second or a third may be done.

NON-TUBERCULAR DISEASE OF JOINTS.

Under the titles of epiphysitis, osteitis of growing bones (Macnamara), epiphysial necrosis (W. M. Baker), necrosis of the extremity of the diaphyses and epiphyses of growing bone (Eve[1]), has been described an acute, subacute, or chronic non-tubercular inflammation of the articular ends of the long bones, often going on to the formation of an abscess and sequestrum and in many cases causing inflammation and destruction of the neighboring articulation. There is no question that there is an epiphysitis of tubercular origin,—in fact, many cases of strumous disease of the bones entering into the formation of joints begin in or about the epiphyses,—but the class of cases now referred to do not belong to this category. The subject is one of importance, and a clear understanding of its pathology, symptoms, and clinical history will throw light upon many cases of joint-affection. Perhaps the term osteitis of growing bones is the more correct, because the epiphyses are not in all cases the real seat of disease, the trouble being sometimes entirely on the diaphysial side of the epiphysial disk. But in the vast majority of cases the epiphyses are either primarily or secondarily involved; the symptoms and influence upon the integrity of the neighboring joint are almost identical whether the disease begins on the one side or the other of the cartilage existing between these two portions of the bone. The term epiphysitis will be used, meaning thereby disease of the bone in the neighborhood of the epiphysial disks. Although epiphysitis is strictly an affection of the bones, yet the situation of the point of the disease is in such close proximity to the joint that the articulation is readily affected; and this fact gives to the study of osteitis in the ends of bones an importance equal to that of primary disease of the joint itself.

---

[1] St. Bartholomew's Hospital Reports, vol. xv. p. 125.

Epiphysitis is a disease of childhood. The peculiar construction of the articular ends of the bone, the active nutritive processes going on in these parts, and their low resisting power predispose the parts to inflammation and necrotic changes. "The medulla filling the areola of the spongy tissue is the real seat of the inflammation; in it we have increased vascularization with exudation. In this condition the parts may remain for some time. In many instances pus is early formed in the vascular medullary tissue; the trabeculæ, which at first maintain their structure, not infrequently necrose. A line of demarcation is formed between the dead and the living portions."[1] In other words, we have a local osteo-myelitis. If the process goes on, a time comes when the circulation will be cut off from a portion of the bone in the centre of the inflammatory area, and its local death will take place, to an extent depending upon the amount of disease; and thus we have at times a sequestrum enclosed in a cavity, with pus between it and the living bone. The tendency of these bone-abscesses is in time to make a way for themselves through the bone and discharge, the amount of local trouble depending upon the acuteness, situation, and duration of the disease. If they are very acute, they soon involve more of the osseous tissue, break through the limiting exudation, and make their way rapidly to the surface in the direction of least resistance, often involving the soft parts; if, on the other hand, they are more chronic in their course, the bone will be slowly thickened and condensed, and it may take years for the abscess to reach the surface.

Between these two types there is every shade of variation. The joint is involved only secondarily. In very acute cases it may be almost impossible to separate the bone- from the joint-trouble, while in more chronic cases the articulation is affected only after some time or not at all. The disease may attack the epiphyses alone, or the articular end of the diaphyses, or both may be involved.

The origin of these cases is often an injury near a joint, as a sprain or a blow. The patient within a day or so complains of acute pain and tenderness over the bone near the articulation, or the symptoms may come on suddenly after the patient has been exposed to wet or cold. There is often swelling about the joint, at times extending up or down the limb beyond the seat of injury. Soon the joint becomes distended, and, if relief is not at once afforded, the articulation is destroyed. Sometimes the case does not pursue so rapid a course, the pain and tenderness upon pressure are much slower in showing themselves, and the swelling of the joint does not appear until much later, or the joint may not become directly affected, as in the following cases.

---

[1] Jones, op. cit., p. 93.

Case I.—A boy eight years of age was admitted into St. Mary's Hospital, giving the following history. Six weeks before coming under observation he was run over by a cart, the upper end of the tibia, near the tubercle, being bruised. In a few days he began to have considerable deep-seated pain in the head of the tibia, the joint became swollen, and finally an opening formed on the anterior aspect of the bone just below the tubercle of the tibia, from which, at the time of admission, there was a discharge of pus. There was seen a small sinus just below the point of attachment of the ligamentum patellæ, through which necrosed bone could be detected. The upper part of the tibia was considerably enlarged. The patient was etherized, and the upper portion of the tibia was found to be converted into a large cavity containing many sequestra. The cavity was bounded above by the epiphysial cartilage and lined with sclerosed bone. In this case the process has been slow, and, although there had been effusion into the joint, the abscess did not communicate with the articulation, being limited above by the epiphysial cartilage, and the joint was only affected by contiguity of tissue.

Case II.—A girl seven years of age came under my care in 1881, with the following history. From some unascertained cause, three years previous she experienced great pain at the lower end of the femur, with marked constitutional disturbance. Later the joint became inflamed, and an abscess opened just above and to one side of the patella. After discharging for some time, the swelling of the joint disappeared, but there has always been some slight discharge from the sinus. No further history could be obtained. The tibia was found dislocated backward upon the condyles flexed to a right angle. The lower portion of the femur was much enlarged. With the patient under ether the sinus was found to connect with the knee-joint. An opening was then made into the articulation; the cartilages were comparatively healthy except at a point between the condyles near their posterior surface, there was exposed bone, and in this was a sinus extending up the shaft of the femur. The soft parts were then detached from the anterior aspect of the bone, and its anterior surface chiselled out so as to expose the sinus. In this way it was laid open almost to the joint. A sequestrum was found in a cavity about the size of a hazel-nut, loose, and consisting of cancellous bony tissue. The sequestrum was just above the epiphysial cartilage. The following evidently was the pathology of the case. From some cause there had been a local osteitis just above the epiphysial disk; this had caused a necrosis of a small portion of the cancellous tissue; later an abscess had formed which finally had opened into the knee-joint, causing suppurative inflammation; the abscess then perforated the capsule and made an opening near the patella where the sinus was found. The abscess in the bone caused it to become inflamed and enlarged. In other words, there had been an acute epiphysitis, followed by inflammatory enlargement of the end of the femur.

Case III.—Recently there has been under my care a child four years of age who, following measles, had disease in the epiphyses of both femur- and wrist-joints, with necrosis. The lower portion of the left femur was considerably enlarged; there was a sinus discharging considerable pus situated just within and under the biceps. On cutting down upon the bone from the lateral aspect of the thigh, an opening was found at the epiphysial line large enough to admit the finger, and leading into a cavity which represented the entire epiphysis, there being only a thin shell of bone separating it from the joint. Within this cavity there was found a sequestrum of the size of an English walnut, representing in shape the bony portion of the epiphysis. There had been an acute epiphysitis at the lower end of the femur, with the death of a small portion of the cancellous bony tissue. The accompanying abscess had made its way into the knee-joint, causing a purulent synovitis. The sinus would not have closed until the sequestrum had been removed.

Case IV.—A child two years old was admitted into St. Mary's Hospital for children during the last year, with the history of an acute swelling on the anterior aspect of the thigh and about the hip-joint. She had complained of no pain and had no lameness until four weeks before admission, when she was seized with acute pain about the hip, accompanied by inability to use the limb. On admission the upper part of the thigh was much swollen and the trochanter was above Nélaton's line. The abscess on the anterior aspect of the thigh was opened; it could not be found that it communicated with the articulation. The hip-joint was then exposed; the capsule was full of pus, and the epiphysis was found loose in the joint-cavity; it was not diseased, and appeared as a smooth disk of bone; the neck did not show much disease.

Epiphysitis may follow a much more acute course. Macnamara[1] reports the case of a boy nine years of age who had, a fortnight before coming under observation, received a severe blow over the region of the great trochanter; he suffered severe pain at the time of the injury, especially when he attempted to move the limb; the pain was, however, less the next day. On the night of the tenth day after the accident, while in bed, he was suddenly seized with violent pain in the injured hip, and three days later was brought to the hospital. His temperature was 103° and 105° F.; his left thigh was slightly flexed and abducted; any attempt to move the limb caused violent pain in the joint, as also did the slightest pressure applied directly over the head of the femur. The patient's thigh was not swollen. During the night the boy was delirious. On the second day after admission the joint was laid open, so as to afford efficient drainage. On passing the finger into the joint "the neck of the femur at its lower part was found separated from the epiphysial cartilage, so that there was a free opening through which pus in the cancellous tissues could escape outward. The patient's temperature fell during the evening. He was discharged at the end of the fifth week, able to walk about without the slightest inconvenience, the movements of the hip-joint being perfect."

Another class of acute cases follow a different course. The pus may get under the periosteum, and strip it from the bone to a greater or less distance; and finally it may perforate that membrane and form deep-seated abscesses in the soft parts, a considerable distance from the point of disease. In these cases the nutrition of the bones does not suffer much at first, and if prompt relief is afforded the parts recover.

In a third variety of cases—namely, those which follow a chronic course—it may be months or even years before the abscess in the bone discharges, or the pus may never be able to reach the surface, on account of the inflammatory hypertrophied processes that it has caused in the bone. These are the cases of abscess of the bone described by Brodie. Some of the cases he reports began as an epiphysitis during childhood. The latter form of bone-disease often begins in or near the epiphysial cartilage, usually from an injury. The symptoms may be at first acute, with much pain; there may be a bruising of the bone or an extravasation of blood, followed by inflammation, then death of a small piece of bone; the more urgent symptoms may then disappear, but the foreign body causes a subacute or chronic inflammation of the bone, followed by hypertrophy. The after-history of these bone-abscesses, so far as the joint is concerned, varies according as the pus works its way towards the articulation or the inflammation of the bone extends to the joint; and thus a very troublesome and rebellious joint-affection is set up.

---

[1] British Medical Journal, 1888, vol. ii. p. 76.

The joint may be affected in one of two ways,—namely, by the opening of the abscess into the articulation, or by the extension of the bone-inflammation to the joint by contiguity of tissue. In the former class the articulation may be suddenly inflamed by the bursting of the abscess into that cavity, thus setting up an acute purulent synovitis; or there may be from time to time attacks of synovitis of a subacute character following an injury or excessive exercise, recovered from by rest for a few days, only to be succeeded by another attack and this again by another. These attacks leave the articulation less and less able to recover, so that in time it becomes permanently distended. Subsequently this serous synovitis may gradually assume a purulent character, so that when the abscess opens into it there will be no marked increase of the symptoms. If the joint is affected by the extension of the bone-inflammation, it may gradually become swollen, but not so markedly as in the case of serous synovitis; it is tender and painful; gradually it becomes flexed and stiff. On opening such a joint, the articular surfaces are often found bound together by adhesions; there may be a slight increase of synovia, but the inflammation is chiefly of an adhesive variety, and recovery with any useful motion is very seldom seen. These are the cases of chronic inflamed joints which go on to ankylosis, either fibrous or bony, with dislocation of the tibia backward upon the condyles of the femur.

The affection may begin (1) just beneath the articular cartilage, (2) in the neighborhood of the ossifying centre of the epiphysis, (3) in the line of the junction of the epiphysis to the shaft, or (4) in the shaft near the epiphysial disk. The nearer the joint the affected tissue is situated, the sooner will it become involved.

Symptoms.—The symptoms of acute epiphysitis are marked, but they vary somewhat, depending upon the situation of the portion of the bone involved. If it is near the epiphysial disk,—that is, some distance from the joint-surface,—the joint will not be affected so early as when near the articular cartilage. The disease commences with intense pain and tenderness over the articular end of a long bone; sometimes this tenderness is confined to or is more marked in one spot. The soft parts are soon swollen in superficial joints, and the articulation itself is often enlarged and the limb flexed. There is a distinct increase of heat over the parts, and constitutional symptoms are marked. Pain is greatly increased by pressure over the bone or by any attempt at motion. Sometimes it is impossible to separate the bone- from the joint-symptoms, so rapid is the course of the disease. In those cases in which the point of the disease is within the articular cavity, it may be impossible to distinguish the disease from acute purulent arthritis.

Pus is soon formed, and in bad cases the inflammation rapidly involves all tissues,—the bone, the periosteum, the synovial membrane, and the soft parts. The epiphyses may become separated from their attachment to the shaft. In a few cases pus finds its way between the periosteum and the bone, and may separate them for a considerable distance from the point of disease. In these cases the limb is more or less swollen, and may have a hard, brawny feel, resembling the condition found in acute osteo-myelitis; later the matter perforates the periosteum and forms abscesses among the muscles. Again, in cases not quite so acute the pus may perforate the bone either outward or into the joint; in the former event it will burrow among the muscles or remain within the periosteum. If it gains access to the joint, acute suppurative inflammation is at once set up, and the symptoms are those of intense purulent synovitis. The younger the child the earlier does the articulation become involved. With acute epiphysitis the constitutional symptoms are marked, the temperature is high, delirium is often present, and the child may die from pyæmia or septicæmia unless prompt relief is afforded. Sometimes the parts beyond the joint are greatly swollen, hard, and œdematous.

The symptoms attending subacute epiphysitis are not so marked, and in its earlier stage the disease may consist only of some pain or aching about the end of the bone; there may be some tenderness on firm pressure, as in those cases where the point of disease is near the surface of the bone. There is but slight if any increase of heat on the surface. The pain is apt to be worse at night. As the abscess approaches the surface the periosteum is swollen, giving the impression that the bone is enlarged; later bone-enlargement may actually occur. There are vague pains at intervals, and some limping in walking; pain often follows use of the limb, so that the patient is disinclined to move about. After rest the discomfort will often diminish, only to recur again upon use of the limb. As the disease advances there is enlargement of the bone, with increased tenderness on pressure and more pain on motion. The joint gradually becomes fixed, and finally the abscess perforates the bone and fluctuation can be detected and it discharges through the skin. If one of these sinuses is examined with a probe, dead bone can often be detected in the end of the bone. The cavity left by the discharge of the abscess varies in size: it may involve the whole articular end of the bone, or it may be confined to a portion of it. With these symptoms the neighboring joint is frequently affected: it will be swollen, tender, and hot. If the course of the abscess is towards the joint, the history is different: the attacks of synovitis are more frequent, marked, and persistent, until finally the abscess enters the joint, often through a very small opening; or the abscess may suddenly burst into the joint, and purulent synovitis be set up without any previous synovial effusion.

The symptoms of chronic epiphysitis are very indistinct, and are often overlooked. The pain is not marked, and is variable: it may be attributed to rheumatism. Gradually after months the end of the bone will become enlarged, and this increase in size may extend up to the shaft. There will be times when the child will complain of pain and walk with some limp; but the pain is not intense, nor is there much difficulty in walking; the pain is more frequently present at night. These symptoms may last for years, the bone gradually becoming thicker and the discomfort more marked, yet the pain seldom being acute. It may not be until adult life that the true nature of the disease is recognized. With these bone-symptoms it may be years before the joint begins to give trouble, though it is tender, swollen, and looks ill shaped, the muscles are wasted, and the bony prominences are marked. It may be somewhat flexed and fixed in its abnormal position by adhesions caused by the chronic inflammatory process propagated from the disease of the bone. The patient is not confined to the house, but goes about with considerable limp; he may have to use a crutch or a cane; or after years the pain may be constant, with exacerbations, so as to confine him to his bed. If relief is not afforded, the disease is unlimited in its duration, or continues until the abscess in the bone finds an exit; but, as the osseous tissue has by chronic inflammation become greatly thickened and often sclerosed, it is impossible for the pus to travel outward, and operative interference offers the only relief.

Persistent or remitting pain, with or without tenderness on pressure about the articular end of the bone, is an important symptom, and, if accompanied by any enlargement, is diagnostic of bone-abscess. As the disease progresses the pain becomes more marked, and is accompanied by exacerbations, usually at night, and increased by previous exercise. The only condition with which it can possibly be confounded is neuralgia of the bone.

The results of epiphysitis, even when it is recovered from, may be marked. When it attacks the end of a bone at a point at which its normal growth takes place, it may cause an arrest of growth in the bone and marked shortening result. On the other hand, instead of causing arrest of growth, it may cause elongation of the bone, due to increased vascularity of the epiphysial cartilage. Marsh[1] calls attention to the fact "that chronic epiphysitis often lays the foundation of a very intractable joint-disease, especially of the knee. Cases are frequently met with in which children eight or ten years of age are found suffering with joint-disease which originated in the extension of chronic inflammation from the adjacent epiphysis when the patient was only two or three years old, and which, though there may have been periods of remission or even apparent recovery, has several times relapsed and the joint gradually become stiff, often deformed, and liable upon any exertion or disturbance of the health to a renewal of the synovial trouble."

Chronic disease of the epiphyses may apparently be recovered from, and the only indication of its existence for years may be a thickening of the bone and perhaps a scar denoting the point where an abscess has discharged, the patient and his medical attendant thinking that a perfect recovery has taken place. In after-years—it may be not until adult life—the bone may take on an acute inflammatory action, and unless the history has been carefully considered the true cause of the inflammation may not be suspected. In these cases the joint is often involved.

---

[1] Op. cit., p. 134.

Treatment.—The treatment of acute epiphysitis must be energetic and prompt. Absolute rest must be rigidly enforced; the limb must be thoroughly fixed by the use of splints, so that there shall be no motion whatever, either in the muscles or in the joints above or below the affected articulation. If there is much swelling, there must be no hesitation about cutting down upon the bone, and, if necessary, applying a trephine, under strict antiseptic rules. If the joint is distended with pus,—and this can readily be ascertained by the use of a hypodermic syringe,—it should be freely opened, washed out with mercuric solution (one in one thousand), and ample drainage afforded. If a diseased point is found in the bone, it should be freely scraped out with a Volkmann's spoon, so that all diseased bone shall be removed, and then thoroughly washed out with an antiseptic solution, a drainage-tube put in, the line of incision brought together with catgut sutures, and an adequate antiseptic dressing applied. It is well to dust the parts with iodoform and to place a piece of gauze impregnated with the same material over the line of the incision, and then the dressing over all. Even if no pus is found, the relief afforded by removing the tension and allowing the inflammatory products to drain off is great. That pus should be evacuated as soon as formed is a rule that applies with greater force in acute disease of the bone than in the same condition affecting any other tissue. If matter has burrowed up or down the limb among the muscles or has dissected off the periosteum, it should be evacuated by cutting down on the diseased point, the cavity disinfected, drained, and dressed as other wounds. After this operation the limb should be fixed again in splints and the dressings changed as soon as they have become soiled.

If the patient's condition does not improve, notwithstanding free drainage and perfect rest of the part, but, on the contrary, ground is being lost, amputation must be considered. In these cases, when the epiphysis has become detached and is loose in the joint-cavity, it should be removed. In all acute suppurative diseases of the joints and bones a supporting plan of treatment, with the free use of stimulants, is imperatively called for.

Where pus does not have free exit, there is danger of pyæmia and septicæmia, and the best way to anticipate their advent is the early evacuation and drainage of any and every collection of matter. In those cases in which the disease is so near the joint that infection of the cavity takes place at once, the treatment is that of purulent synovitis.

Subacute and chronic epiphysitis do not call for as active treatment as the more acute forms. In the early stage, before pus is formed, absolute rest to the limb by means of splints will often prevent further advance of the disease and effect a cure.

Fly blisters, or the Paquelin cautery lightly applied, may be of use, but rest must be our main reliance. If the pain continues and the bone is tender over a certain point, and especially if it is enlarged, pus has in all probability formed, and a cure is impossible until it shall have been evacuated. With such a history, the best course is to expose the bone over the tender or enlarged point, apply a small trephine, and evacuate the abscess. In case the trephine does not strike the pus, a small curette or some sharp instrument may be thrust in different directions, and in this way the abscess discovered. It is then to be well scraped out, disinfected, drained, and dressed like other wounds. If a sinus has formed, it should be enlarged and a sufficient amount of bone removed, so that its cavity can be well curetted and good drainage afforded. In cases where we find the bone surrounding these cavities sclerosed, it is better not to perforate the hard shell, as thus we might enter the joint or start a new point of trouble in the bone. With proper treatment, subacute and chronic epiphysitis may never involve the joint and no further trouble may ever be experienced.

EPIPHYSITIS OF INDIVIDUAL JOINTS.

Epiphysitis of individual joints, except that of the hip, requires but short notice. Acute epiphysitis of the hip-joint is a serious disease: the articulation seldom if ever escapes. This is due to the anatomical fact that the epiphysis and neck of the femur are within the capsule, and any acute inflammation of this bone soon involves the articulation. The epiphysis is more liable to become detached from the neck than in any other joint, and when this occurs dislocation of the remains of the upper part of the femur almost always takes place upon the dorsum of the ilium.

The symptoms of acute epiphysitis of the end of the femur are acute pain, flexion, and generally abduction; the parts are soon swollen, and pus forms early in the course of the disease; there is marked constitutional disturbance. The abscess soon perforates the capsule, and, if unrelieved, forms large collections of matter in the soft parts, and this sooner or later discharges through the skin. Long before this the epiphysis has been detached from its connection with the neck and lies loose in the cavity of the acetabulum, and the upper end of the femur is drawn up by muscular action and position on to the dorsum of the ilium: this displacement of the remains of the neck of the bone may take place suddenly.

If one examines a joint under these conditions, it will be found, by traction of the limb downward, that the parts can be placed in their normal position, and, while there, crepitus can be detected from the rubbing together of the neck and the detached epiphysis; on withdrawing the extending force the decapitated neck again becomes dislocated upon the ilium. Sometimes the upper end of the femur will not leave the cavity of the acetabulum until the child begins to bear weight upon the limb, when it will suddenly become displaced and shortening be found. In some cases the sinus formed by the discharge of the abscess will close, and nothing will remain to denote the occurrence of epiphysitis but a displacement of the femur upon the ilium and a small scar the remains of the sinus. Unless carefully examined, the scar may be overlooked, and the cause of the malposition of the bone not be understood. Generally the sinus does not close, but continues to discharge more or less pus for an indefinite time, or until the necrosed epiphysis is removed. For a time the limb can be brought down and the shortening temporarily obliterated as long as the extension is kept up. But later the parts will form adhesions to the ilium, the shortening cannot be overcome, and the limb becomes flexed or adducted and often rotated outward, so that the child often has to use a crutch in getting about.

If these cases are seen early and the joint is opened as soon as the swelling becomes marked, the disease may be cut short and a recovery with a useful limb may result, as in the case of Macnamara mentioned on page 1231. But if not seen until the joint becomes disorganized, free incision will save the child much suffering and shorten the time of recovery, although it may not prevent dislocation. If the epiphysis is found loose, it should be removed and the limb held in position by extension, and, later, a hip splint applied and worn for a year or more, in order that the remains of the head and neck may form firm adhesions to the rim of the acetabulum and thus tend to prevent future displacement.

ACUTE EPIPHYSITIS IN INFANTS.

Acute epiphysitis in infants differs in some respects from that occurring in older children, not so much pathologically as in the rapidity of its course, the early implication of the joint, the intensely purulent nature of the inflammatory process, and its great danger not only to the integrity of the limb, but also to life itself. Mr. T. Smith,[1] under the title of "Acute Arthritis in Infants," first described this affection, and later Baker[2] and Marsh[3] have reported cases.

It is a disease of early life, and its interest consists in the liability of its earlier symptoms to be overlooked. Of thirty-four cases it was first noticed in one case on the fourth day after birth, in one on the tenth day, one on the twelfth day, one on the nineteenth day, one at three weeks, one at four weeks, one at five weeks, one at six weeks, one at seven weeks, two at nine weeks, one at ten weeks, one at two months, one at three months, one at four months, one at five months, six at six months, two at seven months, two at eight months, one at nine months, one at eleven months, two at one year, and one at thirteen months. Of these, seventeen recovered, some with perfect joints and some with considerable shortening and more or less crippling of the limb (one recovered after amputation at the lower third of the thigh), and sixteen died,—a mortality of a little over forty-five per cent. In only two cases could any cause be assigned, and in these the joint-affection came on after an injury. It is probable, however, that traumatism is more frequently the cause of the disease than statistics would seem to prove. The tender age of many of the patients, and the ease with which any slight injury may be overlooked or the cause of the pain misinterpreted, tend to obscure the symptoms of the early stage of articular inflammation; moreover, it is often impossible to obtain a reliable history of these cases. The hip was primarily affected in eleven cases, the knee in fourteen, the shoulder in five; in one case both hip-joints were involved when the patient was first seen, in one the hip and shoulder, in one the hip and knee, and in one case (a child twelve days old) many of the epiphyses were found infiltrated with pus on post-mortem examination. The cause of death was either exhaustion or pyæmia, and with the latter two or more articulations were often affected.

[3] Diseases of the Joints.

The history of these cases is characteristic. After a day or so of fretfulness it will be noticed that the child does not use one of its limbs and that it will cry upon any movement of that extremity or of the body; in another day or two swelling around one of the joints will be observed; this will rapidly increase, and sooner or later, if not relieved, the abscess will open and discharge. With this there will always exist high fever and marked constitutional disturbances.

The etiology of this affection is not satisfactorily known. Marsh (*op. cit.*) states that it appears "sometimes to be due to pyæmia or some other form of blood-poisoning, and sometimes to injury during birth or to a subsequent strain or wrench." Owen expresses a similar opinion. From the identity of the lesions found at post-mortem examination with those of epiphysitis in older children, it is reasonable to attribute them to the same cause,—namely, in the vast majority of cases, traumatism,—and to suppose that the pyæmia so often seen is due to infection from the articulation first affected. Epiphysitis in infants is more rapid in its course than in older children, from the fact that the epiphyses are more cartilaginous and are situated more within the articular cavity than in those whose development is further advanced. The conditions found on post-mortem examination resemble those found in older children; but they all show, according to Mr. Smith, a considerable and rapid loss of substance in the articular end of one of the long bones entering into the formation of the affected joint. Sometimes a small abscess is found in the epiphysis communicating with the joint through a small opening; in other cases the whole epiphysis has been excavated, leaving only a shell of bone and a large irregular opening into the joint. If the disease is further advanced, the epiphysis may be detached and the inflammation extend to the end of the other bone. The articular cartilage may present an almost normal appearance except over a limited surface, where an irregular loss of substance may be found leading into a cavity in the bone; or there may be only a small "pin-hole" sinus in the cartilage, through which the contents of the abscess have gained access to the joint; while in more severe cases the whole cartilage may be destroyed and nothing remain but the end of the diaphysis. Sometimes only the ossifying centre of the epiphysis is destroyed, or it may exist as a necrosed piece of bone. The abscess may be confined entirely to the epiphysis or may encroach upon the osseous structure of the diaphysis. Thus we have an acute osteitis of the epiphysis or the lower end of the diaphysis which has gone on to the formation of pus and death of the bone over a larger or smaller extent of surface. This abscess has burst into the joint-cavity through an opening of varying size, depending upon the location and extent of the local trouble; this has caused acute purulent inflammation of the articulation. In some cases the whole limb below or above the primary seat of disease may suffer.

There is a case reported by Brown,[1] of a child eight months old who was quite well in the evening, but became fretful during the night; the next day the knee-joint was swollen and exquisitely painful to both touch and motion. On examination the limb was found enlarged, semiflexed, and so tender that the least touch elicited cries from the patient. By the next day the swelling had increased and had extended up the thigh and down the leg, and by the sixth day the tumefaction was most marked from a point two inches above the patella down to the malleoli. An opening evacuated seven ounces of pus from the joint; the epiphysis of the tibia was found separated from the shaft. Later the limb was amputated through the lower third of the thigh. On examination of the amputated limb the epiphysis was found to be detached from the tibia, and the entire shaft denuded of periosteum and necrosed. There was a pin-hole opening through the epiphysis into the joint at about the centre of the external semilunar cartilage; the articular cavity was otherwise healthy. In the head of the tibia was found a cavity, and from this a small sinus leading to the joint; the whole diaphysis of the tibia was necrosed. In this case there was at first an acute epiphysitis, with abscess; this opened into the joint; then followed acute purulent inflammation of the periosteum of the tibia, due probably to an extension of the inflammation from the epiphysis, and subsequent death of the shaft of the tibia, the course of the disease being exceedingly rapid.

In the report of the post-mortem examination in other cases, lesions not so profound as those mentioned above were found.

Symptoms.—The attack is ushered in with restricted motion and usually flexion of the affected limb, followed by pain, swelling, and rapid suppuration within the articulation. The disease comes on suddenly, and, as a rule, runs a rapid course. Some cases have proved fatal in one week after the first symptoms were noted; in others an abscess has formed in the soft parts and opened within the same period. In Brown's case, cited above, the joint was disorganized by the fifth day, while in other more chronic cases the disorganization has not taken place for weeks. The swelling may be confined to the joint or may involve the parts above and below the articulation. The constitutional symptoms are very marked. Sometimes the skin is red over the swelling; in other cases the hue is not changed until pus has perforated the capsule and is approaching the surface. Sooner or later, depending upon the acuteness of the attack, the matter perforates the capsule, and either finds an outlet almost immediately through the skin, or burrows among the muscles, forming often very large collections of pus. If free exit for the pus from the joint is not afforded, the articulation becomes completely disorganized, in the acute cases at least, within a few days. A joint may thus be hopelessly ruined within a day or so; while in less acute attacks it may be weeks before the capsule is perforated, and even in these cases a recovery is possible, with a perfect articulation. Where a spontaneous opening has been made by the pus, improvement is often very rapid, and the discharge ceases sooner than it usually does in cases of suppuration within the cavity of the joint.

---

[1] Transactions of the Chirurgical Society, London, 1876, vol. iv. p. 175.

The only disease with which acute epiphysitis can be confounded is acute rheumatism. Such being the condition of the bones in fatal cases, it has been asserted that acute inflammation of joints in infants which recover is not due to an epiphysitis, but belongs to another class of articular disease. On this point Mr. Baker (*op. cit.*) makes the following statement. "It may be said in cases of acute arthritis of infants in which recovery takes place, that necrosis is assumed without sufficient reason, while perhaps the fact is rather that recovery is an indication that no actual death on the part of the bone has occurred. It may be so, but such is not my opinion. The cases in which necrosis is proved to exist resemble so closely in their general course and symptoms those in which recovery occurs, that I cannot doubt that the difference is one only of degree. In one the dead bone is so large, and the integrity of the end of the bone so much interfered with, that amputation becomes necessary; in the other the destruction is so slight that with the escape of a few drops of pus and disintegration of a mere crumb of dead cancellous tissue the primary disease comes to an end."

It is evident that in the early recognition and prompt treatment of acute epiphysitis in infants lies the secret of success in cutting short the disease and saving both life and limb. Restricted motion in a limb of an infant should always excite grave suspicion, and, if accompanied by fixation, is almost positive proof of articular trouble or of disease in close proximity to the joint. When swelling is present, the disease has advanced, the joint is in all probability involved, and we have to do with a purulent articular disease. The treatment of acute epiphysitis in infants must be prompt, no matter how young the patient may be. Absolute rest must be enforced by means of splints, and, if we are satisfied that pus exists in the joint, free incisions should at once be made, the cavity disinfected, a drainage-tube inserted, and the joint fixed and dressed antiseptically: the earlier this is done the better are the chances of saving the joint. The course of the disease in many cases is so rapid that delay of even a day in affording an exit for the pus may jeopardize the articulation. The relief thus afforded is frequently followed by rapid improvement in all symptoms, and, although the swelling may be great and the local and constitutional symptoms marked, recovery will take place with a normal joint. The peculiarity of these affections consists in their acute course and their prompt response to proper treatment. If there is much swelling of the limb above or below the joint, it is probable that pus is burrowing either among the muscles or beneath the periosteum. In such cases incisions should be made, so as to afford exit for the matter. Where the disease pursues a much more chronic course, incisions may be put off longer. The integrity of the joint, even in the most acute cases, is often preserved with normal motion.

SHOULDER-JOINT.

The shoulder-joint resembles in some respects the hip-joint: it is a ball-and-socket joint; it is attached to a comparatively short bone, the scapula; the humerus forms the long arm of a powerful lever when the scapula is fixed; but the articulation is not called upon to sustain any weight, as is the hip-joint, and thus intra-articular pressure is not so marked when the patient is up, and when the arm hangs down by the side. The epiphysis is within the cavity of the joint, so that any disease of that portion of the bone is almost sure to involve the articulation.

The joint may be the seat of acute or of chronic trouble. The disease may begin in the synovial membrane or in the bone.

SYNOVITIS.

Acute synovitis is rare in children, and, when it does exist, is due to traumatism or cold. Its symptoms are stiffness, pain, swelling, and heat. Restricted motion is an early symptom, and is soon followed by pain and swelling. The pain is either confined to the joint or is referred to the middle of the arm above the insertion of the deltoid. In acute troubles it is usually severe. The swelling gives the shoulder a rounded or globular appearance. The deltoid seems much fuller than that on the sound joint. Pain is increased by any movement of the arm or by pressing the articular ends of the bone together. The parts are hotter than normal, and fluctuation can often be detected in the joint. The arm is held by the side of the chest, that being the most comfortable position. In moving the arm the scapula is found to move with it.

The treatment of acute synovitis consists in rest and cold applications. The arm is fixed to the chest by means of a bandage, the elbow being flexed and supported on the chest: a splint moulded so as to fit over the shoulder, and securely fastened by bandages to the chest, is useful. A simple synovitis seldom becomes purulent.

Purulent synovitis is usually due to a wound, or comes on in the course of scarlet fever. Its symptoms are simply those of acute serous synovitis intensified, with the addition of redness or œdema about the joint. It may begin with a chill, and is accompanied by a much higher temperature than the simple form of the disease. When it comes on in the course of scarlet fever or any of the eruptive diseases, it is a serious condition.

Treatment of purulent synovitis of the shoulder differs in no respect from that of the same affection in other articulations. The joint must be opened, disinfected, and drained. Marsh considers that in this condition supervening on scarlet fever the indications are to let it alone unless the destruction is marked.

TUBERCULAR DISEASE.

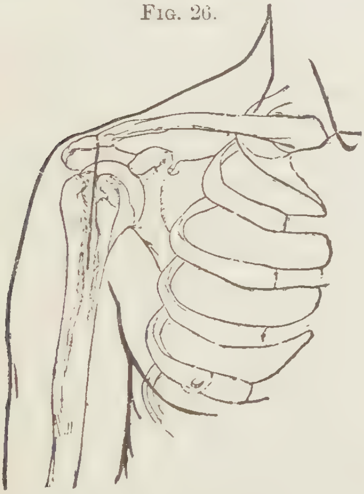
Tubercular disease of the shoulder is sometimes met with in children, and, like all affections of this nature, it is slow and insidious in its development. It may begin in the synovial membrane or in the bone. Marsh states that it usually begins in the synovial membrane, but in the few cases that have been under my notice it has started in the bone. Its pathology is the same as that of tubercular affections of other articulations.

The symptoms of disease beginning in the synovial membrane are stiffness, swelling, pain, and restricted motion. Restricted motion is an early symptom, but care is required in order to detect it. It must be remembered that, even if the shoulder-joint is fixed, the arm may be movable over almost its normal range of motion, on account of the loose attachment of the scapula to the back, the arm and the scapula moving together. Hence, when testing the amount of restricted motion at the shoulder-joint, the scapula should always be fixed with the hand. Pain is variable, as in strumous disease of other joints. When it is present it may be in the articulation itself or at the insertion of the deltoid in the humerus. Atrophy is always a prominent symptom. The deltoid is more or less wasted, as well as the scapular muscle, and this is an important symptom. The arm hangs down by the side of the chest if there is much pain; otherwise the patient apparently moves it, but on examination it is found that the motion is in the scapula. When disease begins in the bone, vague pains are often complained of, usually at night, and the joint is a longer time in showing symptoms of disease. After it has become involved its appearance will be that of disease beginning in the synovial membrane. In osteitis of the head of the humerus there will be considerable atrophy of the muscles before any marked swelling in the joint can be detected. Abscesses usually form in the joint; the pus may escape by the side of the long tendon of the biceps. They are said to be less liable to form in disease beginning in the synovial membrane.

The treatment of disease beginning in the bone is rest, the same as that of the synovial variety of the disease. If the joint becomes involved and pus forms, it should be evacuated, the joint washed out, and good drainage afforded. In cases beginning in the bone the epiphysis is often detached and lies loose in the joint-cavity. In such a case it should be removed. Often the centre of the end of the bone will be destroyed, its shell being left. In case of caries of the head an operation of any magnitude is not required, nor any extensive gouging, a free exit for matter being all that is, as a rule, called for. If, however, a regular excision is demanded, the muscles about the joint should be interfered with as little as possible, and great care taken that the deltoid is preserved, as there is always great danger of dividing some of the branches of the circumflex nerve and thus paralyzing that muscle. MacCormac speaks well of the subperiosteal method of operation when the disease does not involve too much bone.

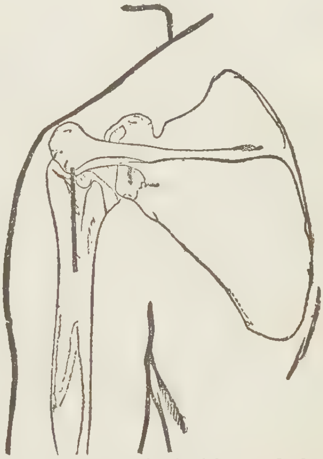
Three incisions have been used,—namely, an incision down through the middle of the deltoid, an anterior, and a posterior. That through the deltoid is always followed by paralysis of that muscle, on account of the necessary division of the circumflex nerve or some of its important branches. The anterior incision is shown in Fig. 26; and here also the integrity of the deltoid is interfered with almost as much as by the central one. Maisonneuve proposed that the incision should be made downward from the external margin of the coracoid process or in the interval between the deltoid and pectoralis major muscles, the vessels and nerves being in such a case pushed considerably inward (MacCormac). The posterior incision (Fig. 27) requires a cut about three inches long. In this operation the circumflex nerve will be divided, and no abduction of the arm can be expected.

Fig. 26.



Method of resection by a single straight anterior incision. (MacCormac.)

Fig. 27.



Position of the posterior incision made for resection of the shoulder. (MacCormac.)

Thus it is seen that radical operations upon the shoulder-joint are beset with dangers in regard to the future use of the arm; and this is the chief reason why excisions of this joint are so unpopular and followed by such unsatisfactory results. In removing diseased bone from the shoulder-joint the operation should be confined to the parts within the capsule as much as possible. If more bone has to be removed than can be reached from within the joint, the periosteum should be stripped off the shaft from above downward, care being taken to preserve as far as possible the attachment of the capsule and muscles to this membrane. After the bone has been removed, a cylinder of periosteum remains connected with the capsule and the attachment of the capsular muscles. The advantage of this method of operating is that it increases the probabilities of a good articulation, and that the muscles are not so liable to retract and draw the cut end of the bone inward to a position beneath the coracoid process, as is apt to be the case in other methods of operating. (MacCormac.)

Excisions of the shoulder-joint have not, up to the present time, been followed with very flattering success, although in a few cases a certain degree of useful motion has been attained.

In the after-treatment massage and electricity should be used, to keep the muscles from becoming more atrophic.

ELBOW-JOINT.

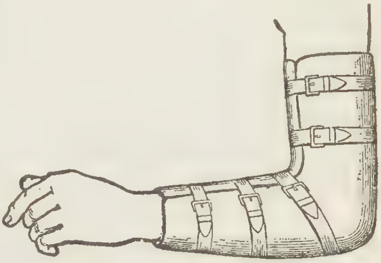
The elbow-joint is in children liable to disease of both an acute and a chronic nature. Inflammation may be caused by a fall, a blow, or a wrench. This would naturally be expected from the exposed position and constant use of the articulation. Fractures into it are frequently the starting-point of strumous disease in those who by inheritance or otherwise are of low vital powers.

ACUTE INFLAMMATION.

Acute inflammation may be due to any of the above-mentioned causes. Its symptoms are restricted motion, swelling, pain, heat, and muscular wasting. Swelling is an early and constant symptom, first noticed on the outer side about the head of the radius and the end of the olecranon, giving to the joint the appearance from behind of being wider than normal; the depressions are also obliterated, especially those on either side of the biceps; later the whole joint is enlarged. When the elbow is the seat of disease, the forearm is held at an angle of about one hundred and thirty or one hundred and forty degrees with the arm; the joint is also fusiform in shape. Active motion at the articulation is early lost if the disease is at all acute. The joint cannot be fully extended. Sometimes rotation is interfered with; at other times it is not much, if at all, restricted. Pain in acute troubles is marked, and the least movement increases the suffering; while in subacute chronic cases it may be entirely absent. The temperature of the parts in acute disease is greatly raised; in mild cases its rise is slight, and in chronic cases scarcely perceptible. Muscular wasting is often marked, and in strumous affections the muscles are greatly reduced in size. Marsh states that "the absence of muscular wasting in cases of suspected disease of the elbow may be taken as strongly suggesting that the joint is not itself affected." An elbow-joint that has been the seat of disease, more especially tubercular disease, presents a very characteristic appearance: the muscles of the arm and forearm are greatly wasted, while the elbow is puffed out and of a fusiform shape.

The treatment of all diseases of the elbow-joint of an inflammatory nature consists in keeping the parts at absolute rest. This is best accomplished by the use of right-angled felt splints moulded to the arm and forearm (as in Fig. 28) and by carrying the arm in a sling. The splints should be removed every day or so, and the parts bathed, so as to keep the skin healthy. If the disease is very acute or there is much pain, the patient should be confined to the bed, with the parts resting upon a pillow. Instead of a felt or leather splint, plaster-of-Paris may be used, but it is not so comfortable as a well-fitting felt splint. Some surgeons advocate the use of leeches, but, as said before, they frighten children. The use of an ice-bag or of cooling applications affords comfort. Our main reliance, however, must be upon absolute rest, the joint being kept fixed until long after all symptoms of disease have passed away. If pus forms within the joint during any acute inflammation, its symptoms will be increased swelling, pain, and constitutional disturbance. There may be œdema of the parts and frequent rigors, depending upon the degree of inflammatory action. With these indications the joint should be examined by means of a hypodermic needle rendered aseptic, and, if pus is found, the articulation must at once be opened, washed out, and drained. Even if suppuration has taken place, the patient may recover with a normal joint if action is prompt.

FIG. 28.



Splint for the elbow. (Marsh.)

TUBERCULAR DISEASE.

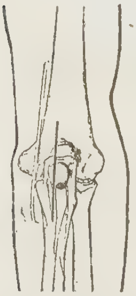
Tubercular disease of the articulation is quite common, and is often very slow in its development. The child may use the limb although the joint may be considerably swollen and pus present in the articulation, but he moves it over a small arc. Disease may begin in the synovial membrane or the bone. In the former case the swelling comes on early; in the latter case stiffness, pain, and muscular atrophy may be present some time before there is much tumefaction of the joint. Even when the articulation is extensively diseased, the child may have considerable use of the arm and may be able to extend and flex it over a greater or smaller arc.

The treatment of tubercular disease of the elbow is rest by means of an angular splint. This should be applied as soon as the trouble is detected. By this means we can often obtain a cure, with motion, even when the disease has made considerable progress. It is often astonishing how much can be accomplished by rest in these cases. An elbow-joint should always be put up at a right angle, for if ankylosis should take place this position is the most useful one.

When the bones are much involved and abscesses have formed in the joint and it is disorganized, a movable articulation is not to be looked for, and excision will afford not only a useful but also a movable joint. An operation is called for when the bones are much diseased, or in synovial affection after the joint has become disorganized and when chronic suppuration is present, or when the joint is ankylosed at an unfavorable angle.

In excision of the elbow a movable articulation is looked for. The operation is not a formidable one, and, if properly performed, the result is good in regard to the usefulness of the limb. In excising the joint certain precautions must be taken. MacCormac advises that "the external lateral ligaments must be preserved if possible, in order to give stability to the joint and to preserve its connection with the orbicular ligaments of the radius, for when these are preserved the future usefulness of the limb is materially enhanced." A long median excision is the best (Fig. 29). A T-shaped one is not only not necessary, but also divides the tissues uselessly. This longitudinal cut should be three or four inches long, made in the median line on the back of the joint, and should divide all structures down to the bone, care being taken that it does not incline too much towards the internal condyle, as in such a case there is danger of injuring the ulnar nerve. All the soft parts are then separated from the bone with a periosteal elevator; the internal flap contains the ulnar nerve, which is but seldom seen; both condyles are thus cleared of all tissue. Marsh states that when the nerve is divided it is done below the joint by cutting among the muscles of the forearm; if, however, the incision is made down upon the posterior border of the ulna, there can be no danger of such an accident. The centre of the excision should correspond to the joint. The triceps tendon is split longitudinally and the capsule opened. The tendon of the triceps is then separated from the end of the olecranon, and thus the interior of the joint is fully exposed. Another important precaution to take is to preserve the anconeus muscle, as this is the only connection between the triceps and the ulna. This muscle after its future development aids as an extensor of the forearm. After freeing all muscles with as little injury to them as possible, the olecranon is removed with cutting pliers; the condyles of the humerus are then detached and removed. The old method of forcing the ends of the bones out through the incision is not an advantage, as the soft parts are more liable to injury than when the bones are divided *in situ*. After the wound has closed firmly, the angle at which the parts have been placed should be changed every few days, and as soon as possible the patient should be allowed to be up with the arm in a sling, and passive motion practised daily.

FIG. 29.



Line of incision in excision of elbow. (MacCormac.)

Partial excisions of the joint have been performed, but usually for injury. Some operators, however, always try to preserve the end of the olecranon.

Pickering[1] performed the operation in the following manner. The joint was exposed in the usual way with a long median incision; the tip of the olecranon was then divided with a chisel and reflected upward. After the removal of the ends of the bone, the tip of the olecranon was united to the ulna by means of a strong wire suture. He reports a fair result at the end of three months. The power of extension was better than that of flexion. This is always the case. The chief defect after excision of the elbow-joint is the often extremely weak power of flexion.

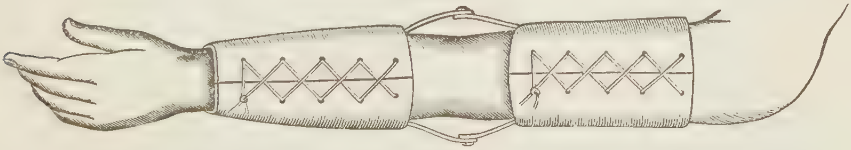
The subperiosteal method of operating is advocated by some surgeons. It is claimed that by this method the joint is more shapely and strong. After the operation the bones must be kept in closer contact, in order that the development of new bone may be greater and thus a larger joint-surface be secured. Passive motion must also be begun earlier, in order to mould the parts better and to prevent ankylosis.

After excision of the elbow-joint the danger is that ankylosis will take place, especially if not enough bone has been removed; on the other hand, the result may be a flail joint in which there is little power of either flexion or extension. To prevent the former, early passive motion should be resorted to. By early is meant as soon as the wound has closed, provided always that it does not irritate the soft parts and cause them to be inflamed, and that it does not cause any discomfort to the patient. The movement must at first be over a small arc, gradually increased daily, and as soon as the patient can execute any active movement he should be encouraged to do so. A splint should not be worn too long.

The best way to guard against a flail joint is to remove plenty of bone, and not resort too early to passive motion. In case a weak joint should result, the bones may be again divided and put in apposition, in order to obtain ankylosis. Care should also be taken that the bones are put at a right angle, as that is the most useful position.

Sometimes there remains a lateral movement at the new articulation. To prevent this, Gerster advocates the use of a simple application as soon as it is evident that there is a defect in this direction. As shown in Figs. 30 and 31, it is constructed in the following manner. "Two strips of hoop-iron or sheet zinc, about one inch wide and from four to six inches long, are

FIG. 30.



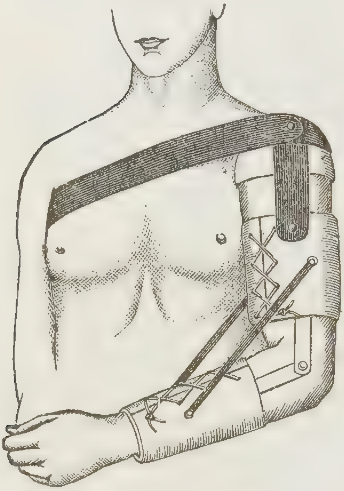
Apparatus for after-treatment of excision of elbow-joint. (Gerster.)

---

[1] Lancet, October 2, 1886, p. 628.

loosely riveted to each other at their ends, so as to form a hinge. Two pairs of hinges are necessary. The patient's arm being protected by a few turns of a flannel bandage, a light silicate-of-sodium wristlet and arm-band (Fig. 30) are applied. To these are fitted the hinges, one externally and the other internally, by giving their middle a suitable bend to allow for the expansion of the soft tissues on flexion of the joint. By a few more turns of the silicate bandage the hinges will become immured in the wristlet and arm-band. As soon as the splint is dry, it is split longitudinally on its anterior aspect, to permit of its removal and further fitting. Shoe-eyelets are put in along the edges of the longitudinal cuts, for lacing. Two pairs of small-sized brass screw-eyes are let in on each side of the wristlet and arm-band, to serve for the attachment of solid rubber bands, which are to aid the effort of the flexor muscles in bending the elbow. To prevent slipping down of the apparatus, a cap is made of a piece of sole-leather softened in hot water, which is moulded to the shoulder. It is then left to dry. A button is let in it to serve for suspending from it the apparatus by a short strap. Another strap over this button is passed around the thorax of the patient and is buckled in the opposite axilla."

FIG. 31.



Splint applied. (Gerster.)

Always after operations upon this joint, extension is more powerful than flexion. Sometimes the latter is so weak that the arm is almost useless. This weakness may result from a lack of support in the cut ends of the bone, due to their small size, which allows one bone to slip over the other; or it may be owing to want of power in the flexor muscles. But, whatever causes it, a firm union between the bone at a right angle will give a much more useful limb.

The after-treatment of the limb consists in strengthening the weak muscles by exercise, massage, and electricity.

ANKLE-JOINT.

Disease of the ankle-joint is common among children, and is due to the same cause as disease of other articulations. The affection may be acute, subacute, or chronic, and of a tubercular or non-tubercular nature, but the former is the more common. It may start in the bones or in the synovial membrane. The ankle-joint is more frequently the seat of injury than any other joint in the body. Notwithstanding this fact, it is not affected with disease so frequently as might be supposed. In children predisposed to tubercular affection, any slight traumatism may be the starting-point of serious disease.

The diagnosis of disease of the ankle is not easy, on account of the proximity of the tarsal bones and joint. Mr. Marsh makes the statement that he has "witnessed more than one instance in which Syme's amputation has been performed under the belief that the joint was disorganized, but in which it has proved that the disease was situated entirely in some surrounding parts."

Disease may begin in the bones or the synovial membrane. It may begin in the tibia, the astragalus, the os calcis, or any of the other bones, the joint being secondarily involved; while, on the other hand, the tarsal bones may be diseased without affecting the ankle-joint, and in making up a diagnosis this fact must be kept in mind, otherwise an error may be made. The presence of a sinus near the ankle-joint is of little practical importance unless a probe can be passed into the joint itself. When abscesses have formed and the parts are swollen, it is very difficult to say whether the ankle-joint is involved or not. When tubercular deposit has taken place in either the end of the tibia or the body of the astragalus, there will be at first slight pain in the parts, with tenderness on pressure; there will be lameness at first only after exercise, with perhaps some stiffness of the joint in the morning, and later occasional effusion into the articulation, disappearing after rest, but finally the joint will become permanently enlarged and lameness will be persistent. Swelling in synovitis of the ankle-joint is easily detected, and is characteristic. There will be swelling in front, where it obliterates all the natural depressions and hides the course of the extensor tendons, at the sides about the malleoli, and at the back, where it fills up the normal depressions on each side of the tendo Achillis. Swelling in the latter position is always present when the joint is distended, and is usually more marked than in any other location: its absence in this locality should raise a doubt as to the joint's being involved.

In tubercular synovitis there may be but little pain; the child will walk with a limp, the foot being held stiff in order to prevent motion in the joint, yet he will not complain of pain. On examination there is often found free and painless motion over the middle range of movement, and it is only when these points are passed that pain will be complained of. As the disease advances the pain will increase and the limp be more marked; the child will not put his foot to the ground, but will go about with a crutch. When the swelling is marked the skin has often a marbled appearance. There is atrophy of the muscles of the leg. The temperature of the parts is variable; sometimes the ankle will feel colder than that of the sound limb. What chiefly attracts attention is the roundness of the parts: all normal depressions are obliterated, and the whole ankle presents a puffed-out appearance. Finally abscess forms and opens.

Disease beginning in the bone has a different history. The pain comes on long before the swelling, and is at first irregular in its character, as is osteitis of the articular ends of other bones; but the lameness is more marked.

The differential diagnosis of disease of the ankle-joint is often puzzling: it may be confounded with extra-articular abscess, with disease of the astragalus, or with inflammation of the sheath of the extensor tendons.

In disease of the astragalus, the scaphoid, or the cuboid bones the swelling is liable to be most marked in front of the ankle-joint, and there is an absence of the obliteration of the depressions at the side of the tendo Achillis. Extra-articular abscesses give still further trouble, because they may surround the ankle-joint; but their history is more acute than that of disease of the joint itself, the pus seems more superficial, and the swelling is liable to extend more forward upon the foot under or along the course of the extensor tendons; further, though at some parts swelling may seem to involve the joint, in other parts the joint preserves its natural outline. The swelling may be well marked in front and on the outer side, but absent from the inner part of the joint (Marsh). A sinus over the joint affords no proof that the articulation is the point of disease; it may be connected with trouble in any other of the tarsal bones, far away from the ankle-joint.

In disease of the sheath of the tendons the swelling is in front and takes an antero-posterior direction, while in disease of the joint the long axis of the swelling is transverse.

Treatment of disease of the ankle-joint, whether it begins in the bone or in the synovial membrane, is the same, and consists in applying a splint or a plaster-of-Paris bandage to the foot and leg and keeping the child from putting the foot to the ground. In fixing the joint, care must be taken that the foot is placed at a right angle to the long axis of the leg, for if ankylosis takes place with the foot either slightly flexed or extended there will be difficulty in walking. With the foot in an extended position the patient will walk with great insecurity, and often with pain; while with it in a flexed position the heel alone comes to the ground. Treatment should be kept up until all signs of disease have long ceased. If the joint becomes disorganized and an abscess forms, it should be opened and the joint-cavity scraped and disinfected. If the bones are involved, the diseased portion can be easily removed.

A regular excision of the ankle-joint, as laid down in works upon surgery, is never called for. The articulation may be examined by making an incision just behind and parallel with the fibula to its lower extremity and thence forward over the front of the foot, the latter portion of the cut only dividing the skin; the external malleolus is then cut off and removed, and the ligaments and capsule are divided, so that the foot can be dislocated inward and its parts reached. If further room is required, the same operation can be done upon the inner side, and thus every portion and recess of the joint reached. I have found that with an osteotome a section can be readily taken from both the astragalus and the end of the tibia. It is, however, seldom necessary to remove a section from either bone, but with a Volkmann's spoon any diseased portion of bone can be taken away. After removing all that is necessary, the foot is put in an antiseptic dressing and fixed at a right angle in some kind of splint.

Operations upon the ankle-joint in childhood generally do well, a useful and movable joint is usually obtained, and there is little if any limp. In case the tendons have to be displaced, care should be taken to replace them and fix the shield by sutures before closing the wound. If the foot at the time of the operation or at any subsequent time should become extended, the tendo Achillis should be divided and the malposition corrected.[1]

---

[1] The writer, in preparing this article, has made very free use of Dr. Gibney's work on "Diseases of the Hip" and of Dr. Howard Marsh's treatise on "Diseases of the Joints."

DISEASES OF MINOR ARTICULATIONS.

By D. A. K. STEELE, M.D.

INTRODUCTORY REMARKS.

In considering the diseases and treatment of the minor articulations, reference will be made solely to those affections occurring in children that implicate the carpal, metacarpal, and phalangeal articulations of the upper extremity and the tarsal, metatarsal, and phalangeal articulations of the lower extremity.

So far as I am aware, there is no essential difference in the pathological processes that take place in the smaller joints of children that would serve to distinguish them from similar changes induced by like causes in adult joints, if we except the greater tendency to repair and the more rapid regeneration of injured tissues that are so uniformly observed in the average child patient. There is, however, the possibility of mistaking an epiphysial separation for a fracture or a dislocation.

We must also remember the risk of causing an epiphysial separation if undue force is used in breaking up adhesions in joints previously inflamed. Owen[1] states that stiffness in joints in childhood almost certainly works off in time, and Paget[2] adds the warning that "children's joints are much more imperilled by violence than those of older patients."

There is, of course, a greater field for the exercise of tact and finesse in the examination and treatment of the diseases and injuries to which their smaller joints are liable. We are not able to go directly at the injured member as we would in the adult, but must first gain the confidence of the little patients before they will permit any examination to be made. We must, if possible, put ourselves *en rapport* with them and be regarded as their friends, and study their unspoken language of signs and facial expressions, if we would patiently yet persistently get the ailments of their minor articulations at our fingers' ends.

Much information is gained by ocular inspection and comparison of the joint while listening to the history of the case from the mother or nurse of the child. Begin the examination indirectly by handling the opposite hand or foot: teach the child by the gentleness of your manipulation of the sound toes or fingers that you are not going to inflict unnecessary pain, and you have gained a great point in the subsequent management and treatment of the case. The first examination should always be thorough, and made in a room with good light and every opportunity for a careful observation of the surface-markings. In case it is necessary to use an anæsthetic, chloroform should preferably be administered, on account of its comparative safety for children, its pleasant odor, and the rapidity with which narcosis can be induced when a few drops are placed on a small linen handkerchief and held closely over the nostrils of a rapidly-breathing child. During anæsthesia and operation the parents should be excluded from the room, as their presence only tends to distract the attention of the surgeon.

ANATOMICAL PECULIARITIES.

The bones are developed from the mesoblast, or middle layer of the blastoderm. "The wrist, or radio-carpal joint, is formed above by the lower end of the radius and the triangular meniscus, below by the upper articular surfaces of the scaphoid, semilunar, and cuneiform bones. An investing ligament, lined by a synovial membrane and subdivided into anterior, posterior, internal, and external bands of fibres, encloses the joint. It is the oblong form of hinge-joint, and possesses two axes, a long and a short. Around the long axis movements occur which bend the hand forward, or bring it in line with the forearm, or bend it backward. Around the short axis the hand may be moved towards the radial or ulnar margin of the forearm.

"The carpal and carpo-metacarpal joints are constructed thus: the articular surfaces are retained in contact by certain ligaments passing between the dorsal surfaces of adjacent bones, by others between their palmar surfaces, and by interosseous ligaments between the semilunar and cuneiform, semilunar and scaphoid, os magnum and unciform, os magnum and trapezoid; lateral ligaments also attach the scaphoid to the trapezium, and the cuneiform to the unciform; similarly the trapezoid, os magnum, and unciform are connected to the metacarpal bones of the fingers by dorsal, palmar, and interosseous ligaments, and the metacarpal bones of the fingers have a like mode of union at their carpal ends. Further a transverse ligament extends between the distal ends of the metacarpal bones of the fingers and checks too great lateral displacement. The range of movement at any one of these carpal joints is very slight, but the multiplicity of joints in this locality contributes to the mobility of the wrist, and makes the junction between the hand and forearm less rigid in its nature. The metacarpal bone of the thumb is not jointed to the index, and has a distinct saddle-shaped articulation with the trapezium, invested with a capsular ligament, so that its range of movement is extensive.

"The metacarpo-phalangeal and inter-phalangeal joints are connected by lateral ligaments passing between the bones, and by an arrangement of fibres on their palmar and dorsal surfaces.

"The movements of the joints are indicated on the surface of the palm by tegumentary folds,—an oblique fold for the thumb and two oblique folds for the metacarpo-phalangeal joints of the fingers. The joints of the second and third phalanges are also marked on the surface by folds.

"The ankle-joint is formed by the convex upper and the lateral surfaces of the astragalus fitting into the concavity formed by the lower end of the tibia and the two malleoli. An investing ligament, lined by synovial membrane, encloses the joint; the lateral portions of this ligament form distinct bands, and are much stronger than the anterior and posterior fibres. A diarthrodial joint also exists between the astragalus and os calcis, between which bones a powerful interosseous ligament passes. Between the astragalus and scaphoid, and the os calcis and cuboid, important diarthrodial joints are found which are enclosed by ligamentous bands. The remaining tarsal bones are connected together usually by dorsal, plantar, and interosseous ligaments, and a similar mode of union is found between the distal row of tarsal bones and the metatarsals, except between the great toe and entocuneiform, where there is no interosseous ligament. The four outer metatarsals are also connected at their proximal ends by distal, plantar, and interosseous ligaments, and further a transverse metatarsal ligament passes between the distal ends of all the metatarsal bones. The metatarsal bones articulate with the phalanges, and the phalanges with each other, in a similar manner to that described in the corresponding bones of the hand. At the ankle-joint movements of flexion and extension take place. . . .

"Between the several bones of the tarsus a certain amount of gliding is permitted, more especially between the os calcis and cuboid and the astragalus and scaphoid, so that it is possible to invert or evert the foot,—*i.e.*, to raise the inner or outer borders from the ground. . . .

"The hallux, or great toe, is the most important digit. A line prolonged backward through it to the heel forms the proper axis of the foot, and the sole chiefly rests upon the pads of integument situated beneath its metatarso-phalangeal joint and the heel."[1]

The epiphysial nucleus appears in the metacarpus and phalanges from the third to the fifth year, and the epiphysis unites in the twentieth year; while in the metatarsus and phalanges it appears from the third to the eighth year, and union occurs from the nineteenth to the twenty-first year.[2]

The four inner metacarpal and metatarsal bones have distal, the outer proximal epiphyses. All the phalanges have the epiphyses proximal. Thus, all the metacarpo-phalangeal joints, save that on the thumb, are on two epiphyses; and so at the foot all metatarso-phalangeal articulations are doubly epiphysial except the hallux.

CLASSIFICATION OF DISEASES OF MINOR ARTICULATIONS.

In accordance with modern pathological views, the diseases of the smaller joints may be classified or divided as follows.

Plastic Inflammations.—Synovitis (simplex), syndesmitis, arthritis, osteo-arthritis, osteitis, teno-synovitis, ganglion.

Chronic Infectious Inflammations.—Tuberculosis, osteo-myelitis, rheumatism, gonorrhœa, syphilis, pyæmia, metastatic.

Acute Infectious Inflammations (*Sequelæ*).—Measles, scarlet fever, smallpox, typhus fever, typhoid fever, cerebro-spinal meningitis, pneumonia, dysentery, diphtheria, erysipelas, parotitis, pertussis.

Tumors.—Chondroma, sarcoma.

PLASTIC INFLAMMATIONS.

As a result of contusions, sprains, or injuries of the minor articulations, we have a variety of simple inflammations that have a natural tendency to recovery if the injured joint is kept at rest. This, however, is not an easy matter in a child: hence the frequency with which we see these simple acute inflammations merge into the chronic forms of disease, the restless activity of the child preventing the necessary quietude of the joint, and the repeated jars and irritations of a damaged joint favoring the localization of infective microbes latent in the blood of the child, until the soil is properly prepared by blood-stasis and aggregation of leucocytes for the segregation and destructive multiplication of infective micro-organisms. In this way we so frequently trace the clinical history of joint-tuberculosis in children, and hence the necessity for prompt, early, and persistent treatment of the plastic or simple non-infectious joint-inflammations of childhood.

The relative strength of the different anatomical structures entering into the formation of the smaller joints of children predisposes to the greater frequency of sprains on the infliction of traumatism rather than to fracture or dislocation. The joint-formation is also favorable to overstretching of the ligamentous structures.

Synovitis.—Simple synovitis involving the carpal, tarsal, or phalangeal articulations is most frequently due to a wrench or sprain, although it may result from exposure, from over-exertion, or from unknown causes. In few affections are the four classical Galenic symptoms of inflammation better exemplified than in an acute synovitis. Heat, pain, swelling, and redness are ordinarily complained of within a few hours after the joint has been injured. The effusion is rapid, and the increased amount of synovia is frequently tinged with blood from rupture of minute intra-articular capillary vessels. Loss of function and tenderness accompany the other symptoms.

Syndesmitis.—In syndesmitis, or inflammation of the ligaments about a joint, there is usually the history of a sprain followed by the ordinary symptoms of such injuries,—pain, tenderness, localized swelling (at first limited to one side of the joint, as a rule), ecchymosis, and immediate loss of function. The pain is instantaneous in character. After a few days plastic crepitus may be noticed, due to peri-articular effusion.

ARTHRITIS.—A simple arthritic inflammation may be caused by injury or exposure, or by an extension of a contiguous inflammation, and gives rise to symptoms closely allied to those described as accompanying synovitis.

OSTEO-ARTHRITIS.—An osteo-arthritis or osteitis is generally caused by a concussion or contusion of the joint and a bruising or laceration of minute blood-vessels or capillary loops at or in the articular extremity of the bone, followed by hyperæmia, stasis, thrombosis or minute emboli, and a localized inflammation that has a distinct tendency to extend to the adjacent joint-surface if absolute rest is not enjoined. The pain is deeper seated, more aching in character, subject to exacerbations, and sometimes the little patient complains only of the joint "feeling tired." There is not much swelling at first, rarely is ecchymosis present, and there is but partial suspension of joint-function.

TENO-SYNOVITIS.—Teno-synovitis is most frequently developed along the sheaths of the flexor tendons of the wrist, although also observed in the extensor sheaths of the same joint as well as around the tendons of the ankle, and is caused by a sudden sprain from a blow or over-lifting or from over-exercise at an unusual or unaccustomed kind of work.

The symptoms complained of are pain, tenderness, and swelling along a tendon-sheath, the pain being increased by movements of the tendon. There is an evident disability of the member at first, but after a few days this is less marked. On palpation, a fine tendinous crepitus, soft and rustling in quality, can be elicited. Congestion, followed by serous and later by fibrinous exudate, marks the pathological changes that are present. The affection usually lasts from one to three weeks.

GANGLION.—Upon the back of the wrist we sometimes find ganglia, either cystic, articular, or merely, and far more commonly, hernial pouches or protrusions through the tendon-sheath at some weak point that has yielded in consequence of a sprain. They are, as a rule, of slow growth, painless, and we are consulted about them more frequently on account of their unsightliness than anything else, although sometimes they cause an appreciable weakness of the wrist and become painful after manual labor. The contents are viscid and albuminous.

The proper treatment of ganglion in the early stage consists of firm elastic pressure by a pad and bandage, and, if this proves inefficient, then subcutaneous puncture with antiseptic precautions, and expression of the contents, with subsequent compression. If refilling occurs, excision of the hernial sac of the tendon-sheath, with strict attention to Listerism, secures a permanent cure. The edges of the sheath should be closed by a fine catgut suture, the external wound closed with silk, and the wrist immobilized for several days. The tubercle-bacillus has a tendency to infect these hernial sacs of tendon-sheaths.

For clinical purposes, all these affections known as plastic or non-infectious inflammations of the smaller joints might be united in one group and described as sprains of more or less severity, involving one or all of the component parts of a joint, according to the severity of the traumatism applied. In the consideration of their treatment we will regard them as so grouped.

Treatment.—The indications for treatment are, clearly, to secure rest, relieve pain, subdue inflammation, and restore the functions of the joint. Complete physiological rest of an injured or inflamed joint is of prime importance. This may be secured in the smaller joints most readily by the application of a moulded, nicely-padded splint, applied so as to include also the proximal joint. In the case of the ankle- or wrist-joint, immobilization is attained by applying a light plaster-of-Paris cast. In all cases smooth, elastic, firm pressure should be obtained by surrounding the joint with layers of cotton batting or absorbent cotton under the fixation dressing. If wounds, abrasions, or blisters are present on the skin, they should be first well cleansed, disinfected, dusted with iodoform, and covered with a layer of antiseptic gauze. When immobilization of the joints of the fingers, hand, and wrist is secured, the forearm should be carried in a sling.

In acute inflammation of the ankle or tarsal joints, after immobilization the patient should remain in bed for some days, or at least keep the foot elevated, and afterwards use crutches until repair is complete.

In the phalangeal joints of the toes and metatarsal joints, immobilization may be secured by wearing a Chinese shoe or a shoe with a Thomas sole or a broad unbending sole, care being taken that it is long enough not to press upon the toes.[1] This, however, is more useful in the chronic inflammations of the joints.

Pain may be relieved by the application of firm elastic compresses, a layer of soft cotton, and over this a flannel bandage or pure rubber bandage drawn with just sufficient tightness to give a feeling of support. Hot fomentations, hop-bags, hot salt, and various anodyne solutions are of advantage, and give comfort to the patient.

Children almost always want "something put on it that will stop the pain." I have found great relief from the use of the following formula in all contusions and injuries around the joints:

℞ Acidi carbolici, ʒii;
Glycerini, fʒvi;
Tinct. opii, fʒvii;
Tinct. arnicæ, f℥iss;
Spts. vini rect. dil., q. s. ad f℥viii.
Apply freely to the injured part.

The internal use of sedatives is also often required if the pain is severe.

Inflammation is lessened by the elevation of the joint, by its fixation, and by the use of compression, hot fomentations, ice-bags, and such other measures as will tend to relieve arterial tension. When there is marked effusion within a joint, aseptic aspiration, with subsequent elastic compression, should be resorted to. It is advised by Martin to apply a rubber bandage around the joint and aspirate between the folds of the bandage, and after the withdrawal of the fluid to allow the bandage to remain on. This is excellent practice, and gives admirable results, especially in the knee.

---

[1] E. H. Bradford, R. W. Lovett Buck's Reference Hand-Book of the Medical Sciences, 1889, vol. viii. p. 368, art. "Joints."

The functions of the joint can be restored by passive motions, friction, embrocations, and especially by systematic massage, which stimulates the adjacent lymphatics to carry away the excess of plastic deposit around the joint that is often the cause of the stiffness. If there is a considerable amount of ankylosis, it is better to anæsthetize the child and completely break up adhesions rather than run the risk of causing additional joint-trouble by repeated inefficient attempts to overcome them. Gamgee advises soft dry sponges applied firmly around an inflamed joint, and then by wetting them efficient firm pressure is obtained that favors the absorption of effused products. Firm continuous pressure favors absorption and atrophy. Intermittent pressure stimulates new growth and plastic exudate. Children regain the usefulness of an inflamed joint in a remarkable manner, and I have been agreeably surprised, in a number of cases where passive motion had to be discontinued on account of pain or the dread of the child to have the joint moved, to find, after a judicious selection of toys or games which would necessarily bring into use the offending joint, that in the course of a few weeks or months the child had " worked off the stiffness," as Owen expresses it.

In teno-synovitis, or thecitis, firm elastic compression along the course of the inflamed tendon-sheath should be applied and secured by a flannel roller. The forearm should be laid upon one of Levis's metallic splints after the compress is applied, or a light plaster-of-Paris cast may be put on, or the forearm may be laid on a padded basswood splint and carried in a sling for a week or two. The disability rarely lasts longer than three weeks.

CHRONIC INFECTIOUS INFLAMMATIONS.

TUBERCULOSIS.—Tuberculosis of the minor articulations usually occurs as a primary osteitis or osteo-arthritis, more rarely as a synovitis. Although generally mentioned as a primary tuberculosis, it is, strictly speaking, a secondary invasion, as the primary dépôt must be situated in some of the lymph-channels before the bacillus reaches bones or joints. The mode of entrance, or " port of entry," of the tubercle-bacillus to the human organism may be either directly through a wound or abrasion, or through a lesion of the mucous membrane of the bronchial tubes, alimentary tract, or uro-genital system. In children invasion takes place most frequently *via* the lungs. No matter what the mode of entrance, we find forty per cent. of the cases occurring as a localized osteo-arthritis.

Tuberculous joint-disease is pre-eminently a disease of childhood. Boys are affected more frequently than girls.

Localization of Tuberculosis.—According to Schmallfuss's statistics relative to the frequency of localization of tuberculosis in the different bones or joints, we find that the foot is affected in nineteen per cent. of the cases, and the hand in eight per cent. only.[1] When we consider that children are peculiarly liable to the sprains and twists and various local minor articular traumatisms that initiate the localization of tubercular processes, we can readily appreciate the importance of this subject and the necessity for its early recognition and proper treatment. Müller has demonstrated that when the bacilli of tuberculosis are present in the blood-current localization takes place frequently in young persons near the epiphysial cartilage by the microbes becoming arrested in one of the terminal branches of an artery, causing an obliteration of its lumen by an embolus of granulation-tissue containing bacilli; or the bacilli may be implanted upon the vessel-wall, and a gradually-increasing mural thrombus obstructs the lumen of the vessel.[2]

The peculiarity of the tubercle-bacilli is to incorporate themselves with a white blood-corpuscle and transform it into a lymphoid cell of larger size.[3] Obstruction of the lumen of an artery in the epiphysis of a long bone leads to the frequently-observed sequestration of a triangular piece of bone corresponding in shape to the area supplied by the vessel. Obstruction of the nutrient artery in the phalanges may lead to death of the entire shaft, especially if the pus-microbe invades the subperiosteal tissue.

Diagnosis.—Generally there is not much difficulty in arriving at a correct diagnosis of tuberculosis of a minor articulation when we take into account the history of the case,—slight traumatism, a neglected sprain or contusion, a subsidence of the acute pain and swelling, followed by a chronic thickening of the joint-structures, and a painless swelling of the joint or near the joint (painless unless overflexion or extension or deep firm pressure is made, which causes pain to be felt). There is an increasing weakness of the joint, extending to the proximal muscles also, which soon become atrophied from disuse.

In case of involvement of the wrist, the fingers are usually kept extended, and there is a marked helplessness about the member; fluctuation is indistinct, and sometimes "boggy" by reason of the mass of granulation-tissue in which coagulation-necrosis has not yet occurred. If the affection originates in the synovial membrane, the effusion and swelling are more marked. There is not much impairment of general health unless the lungs are the seat of miliary tubercles. There is not much tendency to ankylosis. Fibrinous flocculi, or rice-bodies, are indications of tuberculosis.

---

[1] Fenger, Journal of the American Medical Association, 1889, vol. xiii. p. 587, art. "Tuberculosis of Bones and Joints."

[2] Senn, Surgical Bacteriology, 1889, p. 185.

[3] Gerster, Aseptic and Antiseptic Surgery, 1888, p. 264.

In the ankle-joint the fungous synovitis with painless abscesses and fistulous tracks, through the mouths of which granulation-tissue protrudes, is the variety most frequently seen.

In the phalanges of the fingers and toes we meet with the central myeloid tuberculosis, or "spina ventosa" of some authors, expanding the compact structure of the bone to a mere shell, and frequently implicating multiple phalanges, with a tendency to epiphysial and articular involvement. This tuberculous osteo-myelitis also affects the metacarpal and metatarsal bones in children.

Weeping sinews or ganglion, communicating with the wrist-joint or existing in the sheaths of the extensor tendons overlying it, are now recognized as a form of tubercular infection of the synovial order, where we have the localization of the floating bacilli in the membrane by capillary embolism or mural implantation.

Tendon-tuberculosis is an appendix of joint-tuberculosis, and merits the same consideration.

Prognosis.—The prognosis in a case of local articular or osseous tuberculosis in a small joint is usually good, especially in children, provided there are no foci in the lungs. There is a natural resistance on the part of the child to disease-processes, a constant antagonism between growth and normal healthy tissue-development on the one hand, and degenerative changes due to the activity of the tubercle on the other, with the fortunes of war pretty constantly on the side of the physiological cell-soldiers. Hence the frequent recoveries from joint-tuberculosis in children, with, to be sure, occasional relapses, but generally a recovery with a lasting memento of the fight in some scars or a somewhat impaired joint that was the scene of the conflict.

Treatment.—Conservatism should be practised in all operations upon the joints of children: erasions, rather than excisions, should be the rule. The underlying principle of treatment in all simple inflammations of joints is rest—physiological rest—until the pathological changes are arrested. The principle of treatment of infective joint-affections should be to minimize the activity of the microbe that is the causal factor of the pathological processes under discussion, and to multiply the tissue-resistance of the child against the ravages of the micro-organisms of disease.

The organism minimizes the activity of the bacilli sometimes in cases where the destructive processes originate in bone near an articular surface; when perforation of the joint takes place, a wall of granulation-tissue is thrown across the joint around the seat of infection, and, if the circumstances are favorable, a wall of cicatricial connective tissue is formed which protects the intact from the infected portion of the joint, and resists the advance of the bacilli, which thus become walled in by their own environment and die a natural death. Of course where such a favorable termination takes place it is probable that the tubercular virus was attenuated by age or suffered from want of a proper nutrient medium. We fortify the resistance of the child's organism by rest, diet, stimulants, and local refrigeration or pressure.

Operative Treatment.—Artificial anæmia of the limb by means of a rubber bandage should precede the operation, the bandage being applied above the affected joint only. In all operations upon tubercular joints strict attention to the details of antiseptic surgery is essential to success: sterilized hands, instruments, and field of operation are most desirable. Because of the opening up of venous channels in tubercular tissue, we are liable to subject the patient to the risks of dissemination of tubercle through the opened blood-channels, if care is not taken to remove thoroughly all infected tissue by knife, scissors, sharp spoon, or Paquelin cautery; moreover, if antiseptic precautions are neglected, pus-microbes are brought in contact with a surface well prepared by previous pathological processes for the development and propagation of suppurative and septic processes that imperil the integrity of the joint or may destroy the patient. Where the wrist-joint is involved, and especially if suppuration has resulted by reason of the invasion of the tubercular tissue by the pus-microbe, the infected joint should be thoroughly disinfected by irrigation with a sublimate solution, one to two thousand, careful cleansing and disinfection of the cutaneous surface around the joint, enlargement of existing sinuses, or a free dorsal or lateral incision over the most prominent part of the distended capsule, followed by a thorough scraping and clipping away of all diseased tissue, infected capsule, and carious bone, then touching all oozing vessels, especially in bone, with Paquelin cautery. Perfect hæmostasis is desirable, but not always attainable. When the diseased tissue is all removed, the joint should be flushed with a fifty-per-cent. solution of compound tincture of iodine, lightly iodoformized, drained with a small perforated rubber drain or twisted bit of iodoformed gauze, closed by a continuous silk suture, complete antiseptic dressing applied, and then placed on a well-padded palmar splint, or, better, a light plaster-of-Paris cast applied, and then redressed every three to five days. Not infrequently a revision of the operation is necessary where some infected tissue has been left. Functional results are better than from excision.

In ankle-joint tuberculosis the astragalus is most frequently primarily infected, and in cases requiring operative interference no attention should be paid to the anatomical outlines of the joint with a view to limiting the operation to a single bone or capsule. Free lateral, slightly-curved incisions should be made that will permit free access to and thorough scraping and curetting of the diseased tubercular tissue. If an abscess has already opened on the instep, as is frequently the case when we are first consulted, the sinus should be enlarged and traced into the joint, thoroughly spooned out, and injected with tincture of iodine. Through-and-through drainage should be provided, and dressings applied and changed as suggested for the wrist-joint.

As a rule, the functional use of the joint is fairly good after these operations. Indeed, if they are done before the articulation becomes pus-infected, and the operative cavity is permitted to fill with a moist clot under perfect aseptic closure, a remarkably good result is attainable. There is always some liability to relapses, and often a necessity for an operation of revision. This should always be done when pale tubercular granulations protrude from drainage-openings, or when cicatrization is slow.

In tendon-tuberculosis, the not infrequent sequel of sprains, the sheath should be freely opened and every portion of it that is infected carefully removed, along with the gelatiniform tissue frequently surrounding it. The tendon itself should be scraped if it is covered with fine, pale, jelly-like granulations, and after the wound has been thoroughly irrigated with a mercuric solution the surrounding healthy muscular and connective tissue should be closed around it with a continuous fine catgut suture, and the integument closed with silk sutures without drainage, the idea being to permit a moist clot to form around the tendon, and, by subsequent careful passive motions of flexion and extension, commenced ten days after the operation, a new sheath is grooved out of or in the blood-clot, and the movements of the wrist or ankle tendons are restored. Better results are obtained upon the dorsal than upon the palmar surfaces. After operations of this kind, for the first week or ten days a firm elastic graduated compress, with immobilization after the application of the primary typical Lister dressing, should constitute the treatment.

A similar plan should be followed in the treatment of "weeping sinews," or localized infected dilatation of the tendon-sheath: all fibrinous flocculi or melon-seed bodies should be removed, and the sheath closed around the tendon after the removal of infected parts.

OSTEO-MYELITIS.—Tubercular osteo-myelitis of the phalanges, or "spina ventosa," sometimes subsides spontaneously, or is diminished by the alterative action of iodine locally; but its manifest tendency is to invade more tissue, to disseminate itself, to attack secondarily the periosteum, and to form indefinite abscesses. The safest rule in dealing with this rather rare form of osseous tuberculosis of the minor articulations is to make a free incision, and chisel and scrape away all infected tissue with very small, specially-selected instruments. Often an excision or an amputation is required; and the invariable rule is permanent deformity or distortion of the digit.

In the milder and earlier cases of osseous or osteo-arthritic tuberculosis of the minor articulations, where the child's organism is physiologically active and its general health good, and where the attack of the bacilli seems to be comparatively feeble, we should be justified in waiting for a reasonable time before advising operative interference, and relying upon complete rest of the affected joint, placing it upon a moulded, well-padded splint, with moderate elastic uniform compression, for a sufficient length of time to enable us to judge of the progress, arrest, or diminution of the infective pathological processes, at the same time improving the child's nutrition, should it seem necessary, by the administration of tonics and nutriments. In that variety where the morbid processes are initiated in the synovial membrane, aspiration and overdistention of the joint with a two or three per cent. warm carbolized solution or with an emulsion of ether-iodoform is occasionally curative, although not devoid of danger. It is safer to trust to elastic compression and fixation of the joint. If the synovitis becomes suppurative, a free incision and persistent warm antiseptic irrigation may save the joint.

Acute infectious osteo-myelitis is distinguished from myeloid tuberculosis by its greater constitutional disturbance, its agonizing pain, involving usually multiple bones and joints, and the rapidity of its course towards suppuration and epiphysial destruction. It is most frequently mistaken in its early clinical history for rheumatism, growing pains, or typhoid fever. As soon as its nature is recognized, the indications for treatment are to relieve tension, lessen pain, and support the strength of the patient. This can best be done by limiting the destructive processes by early incision, opening up the epiphysial ends of the affected bone, scraping and disinfecting the medullary canal, and iodoformizing the infected area. Good drainage, fixation of the joint, and elevation of the affected part, with frequent change of dressings, constitute the most efficient treatment. Metastatic abscesses, pyæmia, and death often close the scene in this terrible disease.

RHEUMATISM.—Rheumatism affecting the minor articulations requires no particular mention, and is amenable to the same rules of treatment that apply to other articulations. Locally, chloroform liniment and camphorated soap liniment freely applied to the affected hands and feet, these being then covered with cotton batting and oiled silk, or enveloped in soft flannel bandages, have, according to my experience, been the most comfortable applications until the systemic treatment afforded relief. Subsequent stiffness of the fingers, wrists, or ankles may be greatly diminished by massage and passive motion.

Arthritis deformans is occasionally met with in the minor articulations of children, but this intractable affection is, fortunately, seldom seen.

GONORRHŒA.—Gonorrhœal infection of joints is usually observed as a synovitis of an essentially chronic character and likely to be followed by more or less loss of functional activity of the joint for an indefinite length of time. Exacerbations are common. The gonococcus expends its surplus energy upon the synovial membrane when it invades a joint. Out of three hundred and eight cases of gonorrhœal joint-infection, the minor joints were implicated one hundred and eleven times. In children it is so rare an affection that I have never seen an example of it under fifteen years of age. If seen, however, it presents the same peculiarities and is amenable to the same treatment as in the adult.

GOUT is unknown, so far as I am informed, among children.

SYPHILIS.—Joint-inflammations in syphilis may develop in either the secondary or the tertiary stage of disease. In the secondary stage the morbid phenomena of synovitis appear, while in the tertiary stage gummata and a resultant peri-synovial hyperplasia, or a later osteitis of a degenerative type, demand our attention. Hereditary syphilitic joint-manifestations are observed more frequently in infants and children, and, according to Schüller, appear as a synovitis with localized patches of cartilage-necrosis, or as an osteo-chondritis along the epiphysial line with coincident periostitis and perichondritis.

The minor articulations are attacked in one-third of the cases observed. A differential diagnosis between rickets and inherited syphilis can usually be made by a history of the case and by an examination of the articular extremities of other bones, and especially of the costo-sternal unions. A history of previous miscarriages on the part of the mother, and of infantile snuffles and syphilides on the part of the child, is corroborative evidence of syphilis inherited by the child suspected of osteo-arthritic syphilis.

The treatment consists in local inunctions of oleate of mercury or mercurial ointment, and the long-continued internal administration of anti-syphilitic remedies, combined with tonics and attention to the hygiene of the child.

PYÆMIC JOINT-AFFECTIONS.—Pyæmic joint-affections, according to Barwell, are almost always multiple, and the smaller articulations frequently partake in the morbid processes. After lasting for a week or ten days, the severity of joint-symptoms is localized in one or two joints, as a rule. The disease is ushered in by pyrexia, rigors, and increased systemic disturbance; not infrequently the infection follows some slight traumatism over the phalangeal articulations. Often I have seen a slight incised or lacerated wound over a phalangeal articulation apparently heal, and a few days later give evidence of pyæmic invasion of the underlying or contiguous joints. The destruction is rapid, and, when there is a history of septic wound followed by joint-infection by the pus-microbe (staphylococcus and streptococcus pyogenes, aureus or albus), free incision, with antiseptic irrigation, is the surest and safest mode of relieving tension and saving the joint. At the same time the internal administration of quinine, iron, and whiskey is clearly indicated. General supporting medication, with local disinfection and drainage, constitutes the best treatment with which I am acquainted.

METASTATIC JOINT-AFFECTIONS.—Metastatic joint-affections are occasionally seen in children after an attack of the mumps. There is an increase of the quantity of synovia in the capsule. The joint becomes stiff, slightly painful, and somewhat doughy. Usually, under rest, equable compression, or hot fomentations, the synovitis disappears in the course of a few weeks.

ACUTE INFECTIOUS DISEASES LIABLE TO JOINT-COMPLICATIONS.

In regard to acute infectious diseases, such as scarlet fever, measles, small-pox, whooping-cough, diphtheria, typhus and typhoid fever, cerebro-spinal meningitis, erysipelas, septicæmia, etc., liable to be followed by joint-inflammations from an infection of the joint by the specific microbes of these different diseases, it may be said that the infection either occurs through the medium of the circulation carrying the infective microbe to the synovial surface, or reaches the joint-surface from a separate focus of disease by the lymph-channels, or by direct extension from continuity or contiguity of surface.

Micro-organisms are found in the diseased joints corresponding to the micro-organisms of the general disease from which the little patient is suffering. This is now the generally-accepted belief of modern pathologists, and the occurrence of joint-complications in the acute infectious diseases is promptly recognized and its treatment based upon this recognition of the essential cause. The general treatment consists in the exhibition of remedies calculated to combat the general systemic infection of the particular infectious disease under consideration that gave rise to the local joint-symptoms, and the local treatment consists of rest, fixation, and elastic compression of the affected joint, or, later, of aspiration, incision, disinfection, and drainage, if extensive disorganization has occurred.

TUMORS.

The minor articulations of children are liable to the development of either chondromas or sarcomas, which may appear upon the joints of the hand from injury, or upon the distal toe-joints from shoe-pressure. They present the same clinical history here that accompanies their development in other localities.[1] The chondromas require complete excision, with removal of the cartilage-matrix, or they will certainly recur.

The sarcomas are usually central or medullary in their origin, although sometimes springing from periosteal or synovial surfaces, are rather rapid in their growth, and require amputation at the proximal articulation of the bone involved.[2]

ANKYLOSIS.

By R. A. KINLOCH, M.D.

ANKYLOSIS (ἀγκύλη, "bent") is a term used to signify a more or less complete fixation of a joint as the result of chronic pathological changes affecting its component parts. The term has, however, been employed in a very indefinite sense, and without regard either to the character of the changes or to the special tissues implicated. Thus, limited movements of joints, the result of contractured skin or fascia, shortened tendons or muscles, induced voluntarily or involuntarily, have been included under the one name. Some authorities qualify the term so as to designate as *spurious ankylosis* all restricted movements of joints determined by changes of tissues exterior to them. Such *extra-articular* conditions may be referred to as complications, but will not be more particularly considered here. In ankylosis proper, the fixation is decided, if not absolute, and the changes are within the joint: the disease is *intra-articular.*

The joint or limb need not be bent, or crooked, as might be implied by the use of the Greek word. The relative position of the bones may vary; that is, the joint may be fixed at any angle, or the limb may be straight.

As the fixation must be decided, the connecting tissue will be limited in length for the union of the respective bones to be close. The firmness of fixation will depend largely upon the character of the uniting tissue,—its histological advance from the original granulation-tissue of inflammation. The terms fibrous, cartilaginous, and osseous ankylosis express this fact. True bony union does away with a joint, the contiguous bones being firmly connected; fibrous union occasions varying degrees of stiffness. The classification *complete* and *incomplete* ankylosis, adopted by some, was determined by the contrast presented by osseous union with an absolutely immovable joint and fibrous union with appreciable mobility.

Under either variety, very different conditions of the joint are found. The tendency of the fibrous form is to become osseous. Cartilaginous ankylosis is rarely met with, and may be looked upon as a transitional stage between the fibrous and the osseous. R. Volkmann described this as seen in young subjects after subacute coxitis without suppuration.

The kind of ankylosis is determined largely (1) by the character of the original cause, (2) by the continuance of the morbid processes to the lesser or greater destruction of tissue, and (3) by the degree of reparative power prevailing in the structures implicated.

Thus, we find the fibrous ankylosis commonly associated with slight injuries, or with strumous or rheumatic conditions. The osseous, on the other hand, follows active pyogenic processes, or septic inflammations consequent upon severe traumatic lesions. Not infrequently, however, the two varieties coexist, and time only may be needed for the larger development of the more highly organized tissue.

In all cases of true *intra-articular* ankylosis a series of pathological changes can be traced progressively to the complete loss of function and final fixation of the joint. The synovial membrane suffers first, as a rule, the inflammation determining plastic effusion, cell-development, and formation of thick granulation-tissue. The adjacent capsule and other ligaments participate in due time in like changes. The articular ends of the bones become infiltrated with inflammatory products; the cartilages have their nutrient supply cut off, so that portions die, while the greater portion of the matrix liquefies under the invasion of the granulation-tissue formed from the synovial membrane and the articulating extremities of the bones; cartilage-cells proliferate and mix with the numerous cells of the granulation-tissue, and pus now occupies the joint. With subsidence of action the layers of granulation-tissue springing from the contiguous bony surfaces coalesce, and thus a fibrous bond of union is obtained. Subsequently ossification ensues, and bony ankylosis is the favorable termination.

In some instances the morbid process begins in the ends of the bones, and, again, at times it originates in the tissues exterior to the synovial sac. The final result, however, is seen in the changes above described, which are to eventuate in bony ankylosis.

The amount of the inflammatory product and its future development vary, and hence the observable variety in the extent of the adhesions and their nature. At times these are delicate and limited to small defined portions of the synovial membrane; or, again, the synovial membrane is practically replaced by stout bands of fibro-ligamentous tissue which closely connect the bones and arrest the function of the joint. More generally, as above described, the synovial membrane has been destroyed, and the fibroid tissue comes direct from the bones, where it has been formed from the granulation-tissue.

In regard to the osseous adhesions we may note equally variable conditions. There may be firm and abundant osseous material uniting the broad contiguous surfaces, the two bones, as it were, being fused into one; or there may exist narrow bridges of bone, with a predominance of fibroid tissue as the connecting medium. In fixation of some joints, as in the vertebral column, the osseous bridges may be entirely outside of the articulation. These cases would not properly come within our definition of true ankylosis, and their occurrence may with some be an objection to the classification adopted.

The secondary changes pertaining to the extra-articular tissues it is not our province here to describe.

Causes.—Ankylosis originates, as we have seen, from arthritis, and, consequently, may be traced to every kind and degree of traumatism of the articulations,—slight sprains or twists of a joint, luxations, contusions, wounds, fractures near or through joints, infective periostitis, osteo-myelitis, epiphysitis, pyæmia, struma, syphilis, contagious fevers, etc. Luxations and fractures are perhaps among the most common causes, being associated with injury of so many of the proper tissues of the joints, and with their long disuse as enforced by certain kinds of treatment, often too carefully and unnecessarily persisted in. That the long disuse of a joint under these circumstances may be a cause of ankylosis we prefer to admit, although the fact is denied by good modern authorities. The exercise of the functions of all organs is necessary to healthy conditions, and the absolute immobility of a joint will assuredly in time lead to troublesome and persistent stiffness, if not to positive ankylosis.

Where fractures penetrate a joint we find (1) a high degree of inflammation following the traumatism, (2) intra-capsular and extra-capsular blood-extravasation, (3) exuberance of callus, and (4) displacement of the fragments of bone and their encroachment upon the joint-cavity. All these hinderances to motion may lead secondarily to contraction of tissues and to true ankylosis. The constitutional causes above alluded to may often be regarded as mere complications determining the character and degree of the changes following upon the traumatism. Tuberculosis, if viewed in the light of a constitutional condition, must also, when met with primarily in the extremities of the bones or in certain other tissues pertaining to the joints, be regarded as a local process directly determining those pyogenic inflammations which are so destructive in young subjects.

Diagnosis and Signs.—In considering the diagnosis it must be presupposed that all acute action has subsided, and that we are not to consider those hinderances to mobility of a joint which are the natural concomitants of such action. It will in this view be no difficult matter to ascertain the existence of that degree of fixation constituting true ankylosis. Decidedly rough handling may at times be necessary to recognize signs, and it is often advantageous to both patient and surgeon to conduct the examination under an anæsthetic. In the hip- and shoulder-joints difficulty arises from the mobility of the pelvis and the scapula. The yielding of bones must not be confounded with mobility of the joints proper.

Chronic osteo-arthritis may be confounded with ankylosis. The history and age of the subject, the joints affected, and the existing deformity will assist in the differentiation of the two affections.

The diagnostic point more generally to be decided has reference to the *variety* of ankylosis: is it the fibrous or the osseous form that we have to deal with? Absolute fixation, without pain upon manipulation, proclaims the osseous form. But at times the fibrous variety gives apparent immobility : so the examination must be carefully made. Some degree of pain with even the slightest yielding of the bones will decide the question. Bony formation outside of a joint, as is seen in the osseous bridges of a diseased spinal column passing from one vertebra to another, may occasion fixation where there is little or no intra-articular disease; or, again, we may be deceived, as in the case reported by Bonnet,[1] where the femur and the tibia were fixed by a large mass of fibrous tissue occupying the popliteal region, the joint being healthy. These cases are so exceptional that they need not affect the classification which accepts only intra-articular changes as necessary to true ankylosis. Where fibrous union is so short and firm as to simulate osseous union, it may be safely concluded that this latter will finally obtain.

The positive differentiation of these varieties of ankylosis is at times a very practical question, inasmuch as a yet mobile articulation may mean continued local and constitutional irritation threatening the life of the individual, while an immovable one offers assurance of the cessation of irritation and gives hope of recovery. A correct estimate of the shortness and strength of the adhesions is also important, because bearing directly upon the treatment.

Treatment.—It is of primary importance to ascertain beyond doubt the degree and the character of the fixation of the particular joint. To this end an anæsthetic will avail much. All extra-articular hinderances to motion (false ankylosis) must be determined, for it may prove necessary to overcome these as preparatory to dealing with the intra-articular condition.

The original causes of the disease, local and general, and in certain cases more especially the septic or the non-septic character of the arthritis which established the ankylosis, must be duly weighed. In some instances the ankylosed condition must be regarded as a conservative result; in others the very tendency to this should be combated by every resource of art, in order to preserve the function of the joint and the usefulness of the limb. Treatment aims at times to restore normal motion and function; or, again, it rests satisfied with an approximation to so favorable a result. In special cases the malposition of the limb is the important thing to overcome. A leg bent at the knee may be a useless appendage, and an extended elbow a source of much annoyance. Such malpositions are often due to want of judicious treatment during the acute stages of the arthritis. This is now so well recognized that modern scientific treatment insists upon the avoidance of such evils. Lastly, as life is more valuable than a limb, the sacrifice of a limb may be preferable to persistent efforts for preventing or overcoming ankylosis or restoring usefulness by correcting malposition.

Preventive treatment we cannot discuss as fully as we should like in the limits assigned to this article. It resolves itself into the proper treatment of the preceding arthritis, acute or chronic. In connection with the important subject of luxations, and of fractures near or involving joints, preventive treatment cannot be too strongly urged. Accurate adjustment of articulating surfaces and of displaced fragments of bone, and the fixation of these for a definite time, will limit effusion and the formation of callus. Extravasated blood must be got rid of by aspiration or by compression and massage. In joints like the knee, the good effects of early aspiration are clearly evident. After the third or fourth day, methodical compression and massage give good results. These should be employed so as not to interfere with proper circulation or the adjusted fragments of bone. The rubber bandage applied directly, or over soft wool or cotton compresses, is most efficient. Splints and bandages may be temporarily removed after a week, and massage practised. Smaller contiguous joints, also muscles and tendons, must be actively or passively exercised once in five or six days, and the splints and bandages replaced. There should be no immobilization of a joint longer than is necessary for due repose and consolidation of the fracture. The time required for immobilization, we believe, is generally over-estimated.

---

[1] Sur les Maladies des Articulations, tome i. p. 130.

Where soft union already obtains, treatment, except in cases where ankylosis is considered salutary, should be directed to preventing this from becoming osseous. Here passive movements, with gentle frictions, careful exercise, and gradual increase of extension and flexion, must be persisted in, if necessary for weeks and months. Any reaction following such movements should be regarded as an indication for longer suspension of exercise and for more moderate and careful manipulations.

In the fibrous form, when deformity and stiffening are marked, attempts must be made to overcome such and to restore the movements of the joint. We may resort to gradual extension by weight and pulley, or some form of screw apparatus. Numerous machines for this purpose have been invented, and can be found illustrated in most of the surgical treatises from the Middle Ages up to the present time. The simpler means are usually the best. The weight and pulley, with or without some kind of rubber extension force, will usually succeed if success is attainable. Preliminary division of tendons, muscles, fasciæ, or cicatricial bands may at times be necessary. No extensive division of such tissues should be made, however, until the use of an anæsthetic has enlightened us as to their extent and strength. Where cicatrices, especially of the skin, are firm, the extension must never be violent. We succeed best in overcoming these by repeated and slow stretching. Should rupture of exterior tissues occur, and an open wound result, the complication becomes most serious.

The treatment by gradual extension is necessarily slow, and in the end it often fails to establish the natural mobility of the joint. A quicker and generally more satisfactory method is by rapid and forcible extension or flexion under an anæsthetic, and at times after preliminary division of tendons. This is the *brisement forcé* of the old authors, and was originally, when practised without anæsthesia, an operation of much terror. At the present day it is efficient as well as attractive. It saves valuable time.

Gentle movements should first be made in all directions, so as to get rid of minor obstacles. Often a sudden rotation or twist of one of the bones insures replacement, with yielding of the rigid structures of the articulation. The hands of the surgeon, alone, or aided by the manipulations of assistants, will usually suffice. At times powerful mechanical contrivances are brought into use.

Pain and swelling, with some reflex excitation of surrounding muscles, naturally follow such operations. The immediate after-treatment should seek to limit or prevent these painful results, and likewise to obviate subsequent deformity or malposition of the limb. A hypodermatic injection of morphine will usually be appropriate.

The limb should be carefully padded and bandaged from below upward, and a suitable splint adjusted to prevent extension or flexion. A plaster bandage at times is preferable to ordinary splints. Whatever contrivance is used, the indication is to *insure absolute rest of the joint*, and, together with this, moderate and uniform compression as an additional aid. We have seen excellent results from enclosing the joint and limb in a soft pillow and binding this tightly around with a bandage.

The immobility and support of the joint must be insured for eight or ten days, or until the swelling and irritation subside; then the further treatment will depend upon the result desired. If mobility of the articulation is sought, passive motion and massage must be carefully commenced; if permanent ankylosis is desirable, the limb must be fixed for many weeks in the position which promises the greatest utility. The judgment of the surgeon must determine the question, and also guide as to the frequency of the movements to be carried on, and as to the use or disuse of splints, bandages, and other apparatus. To relieve the pain and swelling following upon *brisement forcé*, or to prevent the occurrence of these, some authorities rely upon ice poultices to the joint, or use the metallic or rubber coil through which iced water is made to flow.

In the hip, knee, and ankle a firm ankylosis admits of a comparatively useful limb, and in directing treatment this must be borne in mind. In the shoulder and elbow there is greater advantage from mobility, and this must be sought by the means already referred to, or even by a resort to resection of the joint.

Bony ankylosis, when consisting only of feeble osseous bands, may be treated by the rapid and forcible method already described. But when the ends of the bones are fused together, or are connected by fibrous bands of great strength, the management must be different. Decided flexion and rigidity at the hip or the knee renders the limb useless, and the extended and immovable elbow admits of but poor use of the arm. A stiff shoulder-joint is not so serious, as the compensatory movement of the scapula, under continued exercise, serves the sufferer admirably well.

Attempts at forcible rupture of adhesions have occasioned subcutaneous fractures of bones above or below the ankylosed joint, and remedied to a large extent the previously-existing deformity. Thus, fracture of the thigh above the knee may enable us to straighten the limb flexed and ankylosed at the knee-joint. As subcutaneous fractures usually unite without difficulty, the practice of fracturing the bone has been adopted as a means of treatment; or, what is better, an osteotomy through the ankylosed joint, or through the bone above, may be resorted to. At the knee, Barton's operation, in which a wedge-shaped piece of bone is removed, enables us to straighten the limb and to treat it as after a fracture; or a subcutaneous section of the femur, above the joint, may be made with the chisel or saw. In the hip the subcutaneous section of the neck of the femur may be made with Adams's saw. A clean resection of the joint at times may be preferable. Resection simply with the view of giving mobility, as often practised at the elbow, is of doubtful propriety. If "all turns out well," as Billroth remarks, "the limb is occasionally quite useful. But this is the point we cannot always insure; and who would risk his life for a stiff elbow?"

DEFORMITIES OF BONE.

OSTEOCLASIS AND OSTEOTOMY.

By A. G. GERSTER, M.D.

I. INTRODUCTORY REMARKS.

THE osseous deformities requiring surgical correction are: ill-united fractures; irreduced dislocations of old standing (Macewen); the various forms of malformation due to rickets, as knock-knee, bow-legs; the various curvatures of the femur and the bones of the leg; pes valgus; and, finally, the pathological condition known under the name of rachitic contracted pelvis. We have to add the many forms of contracture and ankylosis of the several joints of the human body due to osteo-myelitic, tuberculous, or rheumatic processes that have run their course either in the affected joint or in its immediate vicinity. Finally, osteotomy or osteoclasis, or both, may be employed, in conjunction with preceding open division of the soft parts, for the cure of club-foot (Phelps).

II. OSTEOCLASIS.

Definition and History.—The artificial production by the surgeon of a *subcutaneous* fracture is called osteoclasis (ὀστέον, "bone," κλάζω, "I break"). Its distinctive characteristic is to be sought in the avoidance of an injury to the integument. That the great value of this feature has been fully comprehended by the surgeons of all ages, is testified to by the early attempts at its intelligent practice, as recorded in the history of surgery, and by the names and descriptions of a number of venerable though clumsy apparatus, as, for instance, the "scamnum Hippocratis," the "tripastum Archimedis," and the "glossocomium Nymphodori."

But until recent times a serious defect in the methods of the procedure militated against the popularization of osteoclasis. Whenever a fracture was to be produced near the middle of a long bone, existing apparatus or manual force gave the surgeon to a certain extent the power of locating the artificial separation in the vicinity of the point of selection. But the nearer he was obliged to approach an epiphysis the more uncertain and risky became the result of his endeavors. Injuries were produced not intended by the operator, and often of a serious character, while the object of his intentions remained unaccomplished.

Manual Osteoclasis.—Recent, badly-united fractures and non-eburnated rachitic curvatures of the shaft of the long bones of children can often be corrected by the use of purely manual power. The hands of the surgeon, after firmly grasping the limb above and below the site of the intended fracture, are steadied by resting them upon the couch or table occupied by the anæsthetized patient. The thumbs in juxtaposition serve as a fulcrum over which the fracture is produced. The surgeon's knee or the edge of the table may also serve as an efficient fulcrum (Tillaux).

Delore, of Lyons, invented a new name for an old thing. His *redressement forcé* or *brusque*, recommended for the correction of genu valgum, consists in the following steps. The patient's limb is so placed upon the table that the external malleolus and the outer aspect of the thigh are in contact with it. In this position the deformed knee represents the apex of a triangle, the base of which is the surface-line of the table. By his hands, the surgeon brings to bear upon the projecting knee sufficient force to cause a separation of the resisting parts. In children and adolescents a separation of the femoral epiphysis results, and the ultimate issue of the procedure is not unfrequently a good one. But after the sixteenth year, when the ossification of the epiphysial cartilages is more or less complete, rupture of the lateral ligament and distention of the crucial ligaments were so frequently observed, followed by greater or lesser laxity and disability of the joint, that the crude and dangerous procedure was generally abandoned. The long duration of the healing process after the use of Delore's method (from two to five months in children) hastened its final condemnation.

The uncertainty and lack of precision in the employment of osteoclasis were sufficiently great to overcome the prevailing and well-founded fear of suppuration of even as ancient authorities as Paulus Ægineta (660)[1] and Avicenna (died 1037),[2] both of whom recommended, for the cure of fractures united in a vicious position, the exposure of the deformed callus and its division by the chisel, in preference to osteoclasis.

It is natural that the comparative ease with which a fracture can be effected in the middle of the shaft of a long bone should invite practitioners to employ it in suitable cases. And so we see G. M. de la Motte and Jan Muys, about the year 1700, practising *osteoclasis by distention* in cases of deformed callus with shortening. About the same time, or later, three German surgeons, Purmann, Bosch, and Oesterlen, perfected this extension method by adding to it a new and fruitful principle,—namely, that of *lateral pressure* brought to bear from above upon the convexity of the deformed mass of bone. Their several apparatus are all based upon the idea of the common book-press.

---

[1] Paulus Ægineta, De Re Medica, Cornaro interprete, liber vi., cap. cix., p. 601.

[2] Avicenna, Liber Canonis, liber iv.

The name invented by Oesterlen for his apparatus is a fair exponent of its simplicity and handiness. It is the nonosyllabic "dysmorph-osteo-palin-klastes."

In the year 1845, Rizzoli, of Bologna, Italy, invented a simplified and very effective apparatus for the production of fractures of the shaft of the long bones. Each end of a steel rod is attached to the limb by a strap. Exactly corresponding to the place where the fracture is desired, a pad is fitted to the limb. On the posterior aspect of this pad impinges a strong screw, playing through a threaded hole of the steel rod. Each turn of the screw tends to depress the pad, which attacks the bone at a place devoid of support; and, the pressure being raised to a sufficient degree, the procedure will terminate in a fracture at the place where the pad is applied. For obvious reasons, this apparatus lacks the qualities necessary for the production of fractures near a joint.

Von Bruns's modification of Rizzoli's instrument, Schneider-Menel's and Heine's apparatus, Esmarch's osteoclast, and Volkmann's engine, consisting of an iron hoop and a long lever, had no characteristics that would markedly distinguish them as preferable to Rizzoli's original osteoclast.

We owe the most noteworthy and indisputable advance of the technique of osteoclasis to Robin,[1] a French surgeon, whose great success was needed to overcome the strong prejudice entertained by his countrymen against the practicability of the procedure, fostered by Dupuytren's erroneous dogma, that the breaking of a callus was impossible after the lapse of sixty days following the fracture to which it owed its existence.

Pousson[2] cites a number of cases in which refracturing of callus was successfully done two hundred, three hundred, and seven hundred days after the original injury. Billroth repaired a badly-united fracture of the leg of a middle-aged woman four years after the time of the injury.

Robin's apparatus consists of a solid board, representing a slightly-inclined plane, which serves as a firm base of support to the entire length of the limb to be operated on for genu valgum. A gutter made of steel is fitted to the superior aspect of the member. Its shallow concavity permits the lateral shifting of the soft parts of the limb, thus preventing undue pressure and bruising of muscles, vessels, and nerves. By means of four threaded uprights and a corresponding number of screw-heads, two strongly-wrought steel hoops, fitting the anterior and posterior edges of the gutter, are made to bear the requisite pressure upon the limb for its immovable fixation to the board. (Fig. 1.)

No fear need be entertained regarding the safety of the soft parts, and the screws have to be brought down with a good deal of force to secure immobility. Pousson has demonstrated the permeability of the popliteal artery during his experiments, by maintaining through it an uninterrupted current of water while the limb was subjected to the utmost pressure by the operation.

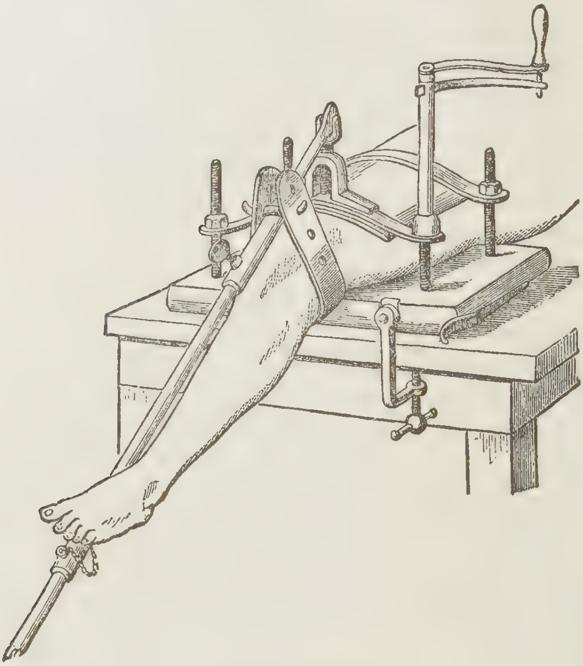
[2] De l'Ostéoclasie, pp. 89, 90, 96, 97.

FIG. 1.



Robin's osteoclast.

The upper part of the femur being thus fixed, a heavy but narrow leather strap is slung about the condyles from below, its ends being caught up by a suitably-shaped clasp of steel. A powerful lever, being now carried through under this clasp, is movably attached to a forked staple resting upon the anterior steel hoops: thus the apparatus is made ready for action. The surgeon grasps the projecting end of the lever, and by a brisk upward movement the fracture is effected, and is attested by an audible cracking noise. The limb, being freed from the apparatus, is immediately encased in an immobilizing splint in a corrected position.

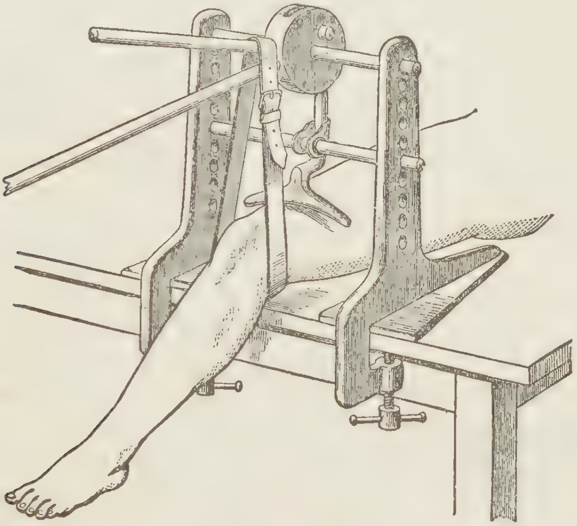
It is evident from the nature of the apparatus that the fracture can take place only where the steel gutter and the leather strap meet.

However precise the action of Robin's apparatus may be, its drawback is, that variously shaped and sized gutters and hoops are required for its application to limbs of different degrees of development. For the hip-joint the principle had to be made practicable by the construction of quite another apparatus, in the use of which the *distal* part of the lower extremity is fixed upon the base-board, the leather strap being applied next to the joint, when by means of two powerful levers a very precise fracture can be produced.

Another Frenchman, the surgical cutler Collin, also invented an osteoclast, in the year 1879; its object was the correction of knock-knee by osteoclasis. It was much inferior to Robin's apparatus in every respect, its *modus operandi* being identical with the process of Delore's method, with the addition of an increased capacity for mischief, due to the augmentation of dynamic power. This apparatus was soon superseded by a second device of the same inventor, which was manifestly fashioned upon the idea embodied in Robin's osteoclast.

Beely, of Berlin, has recently increased the number of known osteoclasts by the construction of a new apparatus,[1] the working of which will be readily understood by reference to the subjoined cut (Fig. 2). As established by a sufficient number of experiments, its action is as reliable and precise as that of Robin's apparatus, and it is suitable for limbs of all shapes and sizes. It is also equal to Robin's instrument in this respect, that the soft parts and the periosteum are not injured, and that the line of fracture is transverse in the main, and not complicated by comminution.

FIG. 2.



Beely's osteoclast.

The newest addition to our osteoclastic armamentarium comes from Italy, where Ferrari [2] has presented what is undoubtedly the best osteoclast for the treatment of knock-knee. Its ingenious simplicity is evident from the illustration (Fig. 3), and its effectiveness is attested by its author and by other writers.

Application of Osteoclasis.—Before entering into the discussion of the merits and limitations of osteoclasis, due mention has to be made of the non-operative, hence slow, method of correcting bony deformities, as promulgated by Sayre in his work on orthopædic surgery. Its value in cases of knock-knee of recent origin, where the eburnation of the deformed bone has not yet taken place, is undeniable. In properly-selected cases its employment will meet with gratifying success.

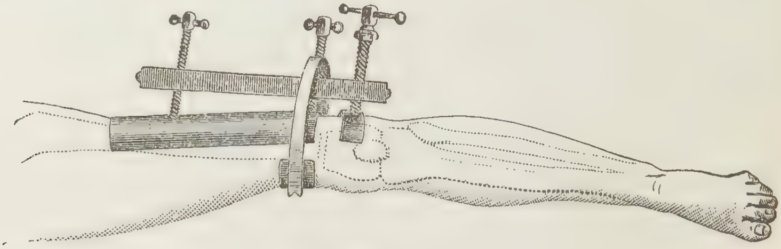
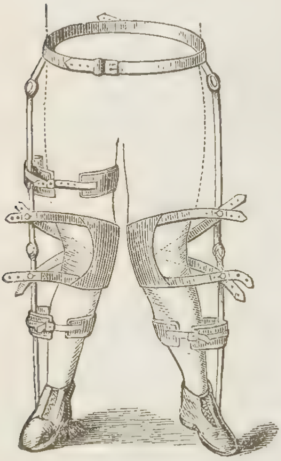
FIG. 3.



Ferrari's osteoclast.

FIG. 4.



Sayre's knock-knee apparatus.

Osteoclasis holds the same relation to osteotomy that obtains between a subcutaneous and a compound fracture. A fracture for the sake of needed correction of a deformity is produced in the former case without, in the latter with, external wounding and its concomitant dangers. It is true that the dangers of osteotomy have become very slight indeed, whenever the surgeon is a competent aseptician. Nevertheless it would be vain to assert that osteotomy is or ever can become absolutely free from the dangers of suppuration. The disadvantage of instrumental osteoclasis as compared with osteotomy inheres in the bulkiness of the needed apparatus, which circumstance is no objection to its use in hospitals, but militates against its application in private and especially in country practice. Another defect of the method is that it is inadmissible in several groups of bony deformities, as, for instance, contractions and ankyloses, for reasons presently to be mentioned.

Let us now examine under what conditions instrumental osteoclasis can be recommended as safe; and, on the other hand, let us see what will contra-indicate its practice.

Instrumental osteoclasis is advisable:

1. In rachitic curvatures of the long bones of children over two years old, which are not amenable to Sayre's treatment by gradual correction on account of advanced hardening or eburnation of the bone.

2. In badly-united fractures of the shaft of the long bones of children and adults.

3. In such cases of knock-knee at all ages as are not amenable to

Sayre's treatment, and in which even the slightest risk from suppuration must be avoided, for various reasons. One of the cogent indications for the selection of osteoclasis would be the unfamiliarity of the surgeon with the antiseptic discipline.

Osteoclasis is not advisable:

1. In contractures and ankyloses of joints previously affected by acute suppurative or tubercular processes (white swelling). The contra-indication here is based upon the fact that the unavoidable traumatism connected with osteoclasis tends to rekindle a quiescent pyogenic or tuberculous focus from latency to full activity. Dangerous possibilities can thus be called forth to mischievous activity, which would remain unprovoked by the gentler though more incisive methods of osteotomy.
2. In badly-united fractures located near and perhaps closely related to a joint, especially where there is chronic joint-trouble caused by the preceding injury. Here, also, osteotomy would deserve the preference.
3. In deformities due to rheumatic joint-trouble.
4. In deformities consequent upon unreduced dislocations of old standing.

III. OSTEOTOMY.

Definition.—Osteotomy is the exposure of a bone by incision, and the subsequent separation of its continuity by means of a saw or chisel. The object of osteotomy is the artificial production of the equivalent of a compound fracture. The injury, however, is devoid of the usual ominous accompaniments of a compound fracture, such as extensive laceration of the soft parts, the comminution of bone, the injury to vessels and nerves, and last, but not least, the frequent soiling and septic infection of the wound by contact, which forms one of the chief elements of danger in accidental compound fractures. In osteotomy there is a clean and small wound of the soft parts leading from the surface to the bone, as a direct and simple continuation of which appears a smooth and straight section of the bone. There is no extensive wounding of the skin or muscles, no pocketing caused by laceration due to the incalculable ways of one or more sharp fragments, wielded by the often enormous forces of accident; antiseptics prevent the introduction of substances apt to inaugurate suppuration, such as do very frequently find their way into the wound in compound fractures. The selection of the site of the osteotomy, and the absence of violence,—in short, the gentleness of the whole process,—insure against accidental injuries, from which few operations are as free as this one, even in unpractised hands.

History of Osteotomy.—As stated in the preceding pages, the first mention of osteotomy is by Paul of Ægina, in 660 A.D., followed by the Arabian Avicenna (980–1037): both of these writers recommended the exposure of a hard deformed callus by the chisel, and its division by the same instrument. After Avicenna's time the operation fell into oblivion for over eight hundred years. Not until 1821 do we find any evidence of its revival, when Wasserfuhr carried out the Æginetan's indication. In 1826 Riecke also performed osteotomy for the rectification of vicious callus.

In America, John Rhea Barton, a Philadelphian, had the courage to take up osteotomy again, and displayed remarkable originality in applying the operation to a new field. Samuel Gross[1] gives the following description of the first osteotomy performed for the cure of ankylosis: "A crucial incision was carried through the integuments over the most prominent part of the great trochanter, when, raising the flaps thus defined, the muscles connected with this portion of the bone were detached, a passage being thus made both in front and behind the femur for the easy introduction of the finger. With a saw constructed for the purpose, the bone was divided through the great trochanter and a part of its neck in a transverse direction." The case terminated successfully. In 1830 Dr. Rodgers, of New York, excised a wedge-shaped piece of bone below the trochanter for ankylosis of the hip-joint, and in 1835 Barton performed a cuneiform osteotomy for the cure of an ankylosed knee-joint. Gross states that "of fourteen cases of this operation of which the results have transpired, twelve recovered, and two perished of hectic irritation and exhaustion respectively. The success would thus seem to be eminently flattering."

The operation met with further development in Germany, where in 1852 A. Mayer published a noteworthy paper[2] on the subject, which seems to have served as an impetus for Langenbeck to perform the operation with the aid of a new principle. His first *subcutaneous osteotomy*, by means of a small straight-pointed saw, was done in the same year for ankylosis of the hip-joint, and was soon followed by a similar operation for ankylosis of the knee. In 1854 we find a record of several operations for rachitic deformity of the leg. Suppuration was the rule in Langenbeck's cases. After Langenbeck a number of modifications were introduced in quick succession by various surgeons. Brainard invented (1854) *subcutaneous perforation of the bone*, which was adopted by Pancoast and Gross (1859) for the cure of ankylosis of the knee. Sayre, of New York, published in 1862 a new procedure for the correction of hip-joint ankylosis, which consisted in the removal of a semilunar section of bone from above the lesser trochanter. In 1868 we see Stromeyer Little in England and in 1870 Billroth in Vienna using the chisel for the first time in subcutaneous osteotomy. In 1869 William Adams divided with a saw the neck of the femur for bony ankylosis, and in 1873 Volkmann performed his first cuneiform osteotomy below the great trochanter.

Although the results of subcutaneous osteotomy were considerably better than those observed after open section, yet the ultimate issue of a vast number of cases was put in great jeopardy by the frequent occurrence of suppuration. If we consider how bulky and clumsy an instrument the saw or a chisel is in comparison with a tenotomy knife, we must admit that most of these operations were "subcutaneous" in name only. As far as safety from suppuration was concerned, they were much inferior to subcutaneous tenotomy.

---

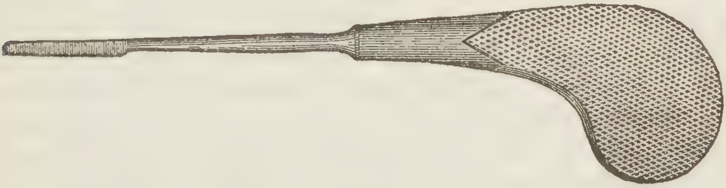
[2] Die Osteotomie als orthopädisches Heilverfahren, Verhandlungen der Med.-Physik. Gesellschaft, 1853.

Volkmann, of Halle, deprived the procedure of its last terror—suppuration—by inaugurating in 1874 the new era of *antiseptic osteotomy.* Macewen performed in 1875 the first antiseptic osteotomy in Great Britain, the second was done by Lister in the winter of 1875–76, and the third by Ogston in 1876 for genu valgum. Barwell, of London, followed in the same year, and since then the operation has been universally adopted as "safe, certain, and most successful" (Macewen).

Application of Osteotomy.—*A. General Remarks.*—Among the great variety of instruments devised and recommended for osteotomy only those will be considered that have met with universal acceptance. They are Adams's saw, the chisel, and Macewen's osteotome.

Adams's instrument, according to his own description, is a small saw "rather more than a quarter of an inch in width, with a cutting edge an inch and a half in length at the end of a blunt shank three inches in length." On account of the simplicity of its use, it is still by many surgeons preferred to any instrument of the chisel order. The weight of Langenbeck's objection, that the bony débris deposited by the saw between the cut bone-surfaces is apt to act as a foreign body, causing suppuration, has been much diminished by the use of aseptic methods, under the protection of which the osseous sawdust is readily absorbed. A more valid objection to the saw is the danger of laceration of the soft parts, with which the instrument must needs come in contact during its to-and-fro movement. But aseptics have rendered even this element of danger very slight indeed.

Fig. 5.



Adams's saw.

The chisel and Macewen's osteotome differ from each other in this, that the former has a bevelled cutting edge, whereas the osteotome has the shape of an attenuated double inclined plane, or a wedge. The chisel, as used by the author, is identical in shape with the ordinary carpenter's chisel, differing from it only by its fine temper.

A solid wooden handle is a great convenience in doing clean and precise work, for which a firm grip is indispensable. A half-inch and a quarter-inch blade will answer every purpose, the rule of safety being, in order to avoid injury by the projecting edge of a too wide implement, always to use a chisel somewhat narrower than the width of the bone to be cut. The temper of the chisel must be that of the tools of the hard-wood- or ivory-carver. The edge of softer stuff will be turned; harder material is apt to snap off in the wound. The best test for the temper of surgical chisels is the femur of an ox. As the principal object of the chisel is the paring of fine shavings and the removal of wedge-shaped sections of bone, its edge should be kept very keen, so as to catch the bone when brought in contact with it.

The osteotome is the true "bistouri des os" (Billroth), or "bone-scalpel," its object being the production of a clean and straight section through any accessible bone in a desired direction. It is a formidable rival of the saw, and the objection that its use requires more skill and familiarity than that of the saw is far overbalanced by the advantages of the absence of bony débris and the avoidance of laceration of the soft parts. Another advantage of a well-tempered chisel or osteotome is the ease with which its edge can be sharpened, without any special tools or skill,—an important consideration in country practice.

Macewen's osteotome, its edge being evenly bevelled on both sides, will, on being driven through bone, not suffer a deflection to one side as an ordinary chisel would, but will maintain its direction unerringly until the section is completed. It "is an instrument of the chisel order, bevelled on both sides, so as to resemble a very slender wedge. The handle and the blade form one piece. The handle is octagonal, which is preferable to the oval or cylindrical, as it affords a better grip, and enables the operator to readily detect any deviation."[1] The top of the instrument has a projecting head. One of the lateral borders of the blade is marked with half-inches, to enable the surgeon to estimate the depth of its penetration. The edge of the instrument should be sharp enough to pare easily the finger-nail. The manner in which the requisite temper of the edge is produced is carefully described by Macewen.[2] If the bone to be divided is very thick and dense, several osteotomes of various sizes are to be used. Macewen's set contains three blades. The thickest is first employed until about one-half of the bone is penetrated; the second, of medium thickness, is introduced into the groove made by the first, and is put aside to admit the third or most slender one only when the deepest layers of bone are to be divided. The osteotome commends itself to the aseptic surgeon's favor by its effectiveness, its simplicity, and the great ease with which the instrument can be kept *absolutely clean*, an advantage not possessed by the saw.

The mallet to be used should be one of hard wood,—lignum vitæ or boxwood. The old-fashioned metal mallets usually furnished by the instrument-makers are too small and too light for serious work.

---

[1] William Macewen, Osteotomy, London, 1880, p. 68.

[2] Op. cit., p. 69.

To the safe performance of osteotomy anæsthesia is indispensable. Whenever possible, artificial anæmia should also be procured by the use of Esmarch's band. Scrupulous asepsis—that is, extreme surgical cleanliness—is to be observed. This is accomplished by the careful shaving, scrubbing, and disinfection of the field of operation and its vicinity. Clean towels dipped in an antiseptic solution are so wrapped about the limb to be operated on as to leave exposed only the amount of space which is indispensable for the performance of the surgeon's work. The surgeon and his assistants and the nurse or other adjuvants should carefully see to the cleanliness and disinfection of their hands and finger-nails; the instruments, especially the saw, should be rendered aseptic by previous boiling, and should be kept ready for use immersed in a three-per-cent. solution of carbolic acid. A stream of irrigating fluid should continually wash away débris escaping alongside of the saw.

After the completion of the section, which if properly done will not cause injury to important vessels, a short pledget of iodoformized gauze is placed over the small wound, and this is enclosed in an ample antiseptic dressing. Esmarch's band is removed, and, if there be no evidence of excessive hemorrhage, the limb is encased in an immovable splint of plaster of Paris or some other material in a correct position. Should the dressings become immediately soaked with blood, exposure of the wound and instant search for the severed vessel, followed by its safe ligature, should be instituted. If the accident has required an enlargement of the external wound, this should be closed, with the exception of so much of its extent as would correspond to the size of the original osteotomy-wound. After this the case should be treated as above mentioned. The patient's comfort will require an opiate for the first and second nights; after that, as a rule, no anodynes will be needed.

The subsequent course of the after-treatment is identical with that of a simple fracture. Fever is rarely observed, although slight rise of the temperature, without sickness, headache, and general dejection, is often present on the second and third days after the operation.

The splint is removed at a time when consolidation is likely to have occurred. The external wound will usually be found healed on the removal of the splint, which, however, should consolidation be found incomplete, ought to be replaced by a new cast.

Regarding the *technique of wielding the saw, chisel, and osteotome* some remarks may be appropriate. The prolonged use of a key-hole saw, of which Adams's instrument is a modification, is extremely fatiguing to one unaccustomed to sawing: hence the surgeon should see to two things in order to husband his strength and to complete the section with some rapidity. The interstices between the teeth of the saw soon get clogged by a sticky paste consisting of fine bone-dust and blood, and, when this occurs, the utmost exertion is needed for continuing the section. It is therefore advisable to have on hand more than one saw, and by changing the implement give an assistant a chance to clear it of débris. As a matter of course, the saws should be properly sharpened before use. Finally, the surgeon should assume that position in which the unusual and prolonged strain of working a small saw through a thick mass of hard bone can be most comfortably accomplished. If these points are observed, undue fatigue will not engender impatience and violent efforts, which, however inefficient in dividing the bone, will certainly lead to unintended injuries by laceration of the soft parts. A proper position of the patient, and a firm fixation, by the assistants, of the bone to be cut, are also indispensable to rapid and clean work.

In using the chisel for the removal of a wedge-shaped piece of bone, a proper bedding of the limb on a cushion (eighteen by twelve inches) loosely filled with dampened sand, and ample exposure of the bone by means of adequate incisions, are necessary. The bevelled side of the chisel should be held towards the part that is to be removed. Attempts at the removal of too large a wedge will lead to splintering of the bone or to the snapping of the chisel. It is more workmanlike to remove many small wedges in succession, methodically deepening the bone-wound to its proper extent. When the division is nearly complete, the remnant of the bony bridge can be snapped off without great effort.

Macewen's osteotomy requires a solid bedding of the limb on a sandbag. The soft parts should be divided by a "sharp, clean, single incision" (Macewen) about an inch long, getting to the bone as directly as possible, and, if feasible, the knife should be carried parallel to the direction of the muscular fibres to be traversed. The knife is to be held *in situ* and not withdrawn until the osteotome is slipped in alongside of it down to the periosteum. Now the edge of the instrument is lightly turned, so as to cross the longitudinal axis of the bone. The locality of the incision ought to be so placed as not to involve injury to more than insignificant vessels. Beginners will do well to make an ample incision, so that the steps of the operation shall be amenable to the control of the finger-tip, or even of the eye.

B. Special Application of Osteotomy.—The indications for the performance of antiseptic osteotomy may be summed up as follows. It is advisable:

1. In cases of badly-united fracture where either the long duration of the deformity or its unfavorable position near a joint renders manual osteoclasis impossible.

2. In cases of bony ankylosis of certain joints, caused either by acute suppurative (osteo-myelitic), by tubercular (strumous), or by rheumatic processes.

This class of cases is especially unsuitable for osteoclasis. Aside from the mechanical difficulty of fracturing the bone in close proximity to a joint, it is to be remembered that considerable traumatism accompanying osteoclasis is very apt to rekindle the process that has led to the formation of the ankylosis. So, for instance, an apparently terminated osteo-myelitis may reappear, or a tubercular affection long since dormant may again become active.

3. For the correction of all rachitic deformities amenable to such treatment the advantage of osteotomy over osteoclasis is as prominent here as elsewhere. It is applicable and successful both in those cases which are otherwise suitable and in those which are unsuitable for osteoclasis.

1. *Badly-United Fractures.*—No specific rules can be laid down for the osteotomic division of badly-united fractures. As regards the general principle of the procedure, it may be said, however, that the artificial division should follow the line of fracture. In those cases of extreme longitudinal displacement where the fracture-surfaces are considerably removed from each other, the object of osteotomy is to divide the callus in such a manner as to produce a condition similar to that found immediately after the accident. After the division of the bone, secure fixation of the limb in a correct position becomes necessary. Where rotary or lateral displacement is the cause of the deformity, reduction and proper fixation in a stiff splint, with or without weight-extension, will be a comparatively easy matter. But where the shortening of the limb is due to excessive longitudinal displacement, followed by corresponding retraction of the soft parts, reduction will not be found easy, and, if accomplished, proper fixation of the fragments will require special measures, such as nailing or wiring. In extreme cases, where the shortening of the soft parts offers insurmountable obstacles, resection of a portion of the continuity of the bone will be necessary to permit easy apposition and fixation.

2. *Ankylosis in a Vicious Position.*—(*a*) *Hip-Joint.*—When there is bony union of the head of the femur with the pelvis as a consequence of precedent osteo-myelitis, tuberculosis, rheumatism, or dislocation, the position of the limb being such that in the erect posture of the patient the foot does not reach the floor, correction is best effected by osteotomy.

According to the preferences of the surgeon the Adams's saw or Macewen's osteotome will be selected. The accompanying diagrams (Figs. 6, 7, and 8) show at a glance the usual places at which the femur is divided for coxal ankylosis. The choice of place for the division will depend upon the peculiarities of each individual case. Where the neck of the femur has been more or less destroyed by disease, Adams's section cannot be done at all. In very fleshy subjects it may be extremely inconvenient, on account of the great depth of the wound. Sayre's plan, simplified by the omission of the laborious and useless removal of a disk of bone from between the trochanters, admits of very general application. Gant's subtrochanteric section seems to be the easiest of the three methods, because the site of the division is most accessible, and the diameter of the bone there is less than between or above the trochanters. Yet each of the three plans is safe, and has yielded excellent results.

The mode of operation is as follows. The anæsthetized patient is placed as for exsection of the hip-joint,—that is, with the ankylosed hip uppermost. The diseased limb is steadied by the interposition of one or more cushions between the lower extremities. All antiseptic precautions being taken, the surgeon makes a short longitudinal incision penetrating to the bone at the site of its contemplated division. If the saw is to be used, the soft parts are peeled off with an elevator from in front and behind the bone, and the section is proceeded with until about three-fourths of the bony mass are divided. The remainder is then snapped off by forcible adduction or abduction. When the osteotome is employed, the soft parts are not to be peeled off, but, the osteotome being introduced along the scalpel held *in situ*, and the latter being withdrawn, the bone is severed by a number of successive taps of the mallet, the last portion of the bony bridge being likewise snapped off, as formerly mentioned. The hemorrhage is inconsiderable. The thigh is brought down so as to occupy a slightly flexed (fifteen degrees) and somewhat abducted (five degrees) position, the wound is dressed, and the limb is secured either in a plaster-of-Paris splint or by weight-extension. According to the age of the patient, consolidation will be accomplished in from three to six weeks.

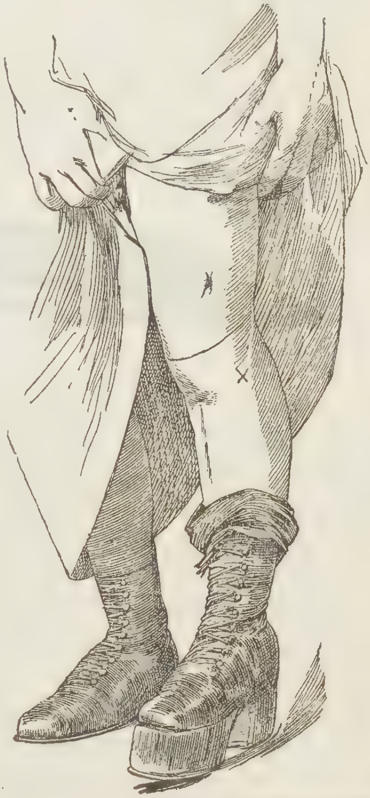
Gant's subtrochanteric section. (Poore.)

(*b*) *Ankylosis of the Knee-Joint.*—Ankylosis of the knee-joint at a considerable angle, whether due to bony union of the femur and tibia or to a cohesion of the patella with the tibia and femur, mostly complicated by subluxation of the tibia backward, and by great shortening of the soft structures occupying the posterior aspect of the limb, requires correction by osteotomy. Here forcible straightening is more dangerous even than at the hip-joint, as serious injury to vessels and nerves is to be apprehended.

Whenever the ankylosed joint forms an angle of less than one hundred and thirty-five degrees, simple osteotomy of the femur will be found sufficient to correct the deformity. Ankyloses of between one hundred and thirty-five and ninety degrees of angularity require osteotomy of both femur and tibia, the result being a straight limb, which, however, presents in front a rather ungainly-looking prominence. The nearer the angle approaches ninety degrees, the more advisable becomes the return to Dr. Rhea Barton's original operation of excising a wedge-shaped portion of bone from the ankylosed knee-joint. This operation, if done aseptically, is not more dangerous than osteotomy, and its ultimate result is infinitely better in every way.

FIG. 9.



Final result after cuneiform excision of knee for ankylosis at a right angle.

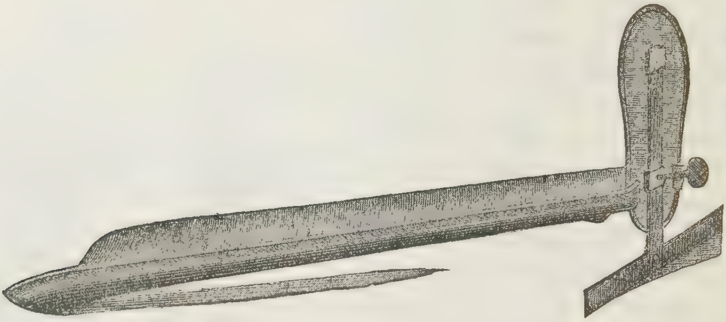
In performing simple osteotomy for ankylosis of the knee-joint, a small longitudinal wound on the outer side of the rectus tendon, on a level with a line drawn transversely a finger's breadth above the upper portion of the external condyle,[1] is made to extend down to the bone; the osteotome is introduced with its blade held longitudinally, then turned transversely; then two-thirds of the thickness of the bone are divided, and the remainder is snapped. If the tibia is to be divided also, the section is made just below the anterior tubercle. The wound is to be made over the anterior tibial ridge, and the tibia is divided transversely. Should the soft parts resist full extension, one or more tenotomies are to be done in addition.

If excision of a wedge-shaped piece of bone be found preferable, a transverse incision, commencing over the middle of one condyle and passing over the patella to the middle of the other, will be found most convenient for the exposure of the parts to be removed. The periosteum is cut along the line of intended section, and then the condylar extremity of the femur and next the tibia are nearly cut through by the saw from in front backward. The remaining bridge of bone is snapped, and, the wedge being removed, the edges of the sections are evened with the saw or the bone-cutting forceps. The sawn surfaces are brought in apposition, and fixation is secured by the use of steel nails driven diagonally through the femur and tibia, and the application of a plaster-of-Paris or a dorsal T-splint. (Fig. 10.) Should the shortened hamstrings offer too much resistance to the correction of the position, one or more subcutaneous tenotomies will have to be practised, until the desired position can be easily maintained. Care must be taken, however, not to injure the popliteal nerve or its branches: if there be any doubt about the identity of the resisting tissues, the safer course will be to expose freely the doubtful band and to make sure before section that it is tendon and not a nerve. The wounds are loosely sutured, an antiseptic dressing is applied, and fixation is secured by appropriate splints, as before mentioned. The dressings are left undisturbed for from two to four weeks, according to the age of the patient. On change of dressings the nails are withdrawn. The usual result is firm bony ankylosis and a very useful limb.

---

[1] Macewen, p. 89.

Fig. 10.



Volkmann's T-splint.

If the wedge of bone is to be removed by the chisel instead of the saw, it is better not to attempt to take away the whole wedge in one coherent mass, but rather to follow a plan similar to that employed by carpenters under similar circumstances. The size of the base of the wedge being outlined by two deepening grooves, the intervening bony structure is gradually chipped away until about three-quarters of the thickness of the bone are penetrated. The remaining bridge of bone is then fractured, and the fractured surfaces are properly pared off.

(c) *Ankylosis of the Elbow-Joint.*—Ankylosis of the elbow-joint in the erect or nearly erect position renders the upper extremity very awkward, and nearly useless for certain purposes, as, for instance, dressing and undressing, and the conveying of food to the mouth. Thus it may be desirable to improve the position and usefulness of the member by decreasing the angle at the elbow. The nearer this approaches a right angle, the better adapted becomes simple osteotomy for the correction of the position; that is, if ankylosis exists at an obtuse angle approaching to ninety degrees, simple osteotomy of the lower end of the humerus will readily permit easy and safe correction. The division should be made from a longitudinal incision commencing at and extending upward from the apex of the internal epicondyle. About two-thirds of the thickness of the bone should be cut with the osteotome in a transverse direction, the remainder being snapped. The arm is then dressed and the elbow put up in a stiff splint at a trifle less than a right angle.

When ankylosis in a nearly erect position is to be corrected, we may either resort to osteotomy of the humerus, radius, and ulna, or, what is better, excise the elbow, when by appropriate after-treatment even a movable joint may be secured.

(*d*) *Ankylosis of the Temporo-Maxillary Joint.*—Osteo-myelitis involving either component of the temporo-maxillary joint may, after expulsion of the necrosed parts, result in osseous ankylosis of the lower jaw and the temporal bone. The patient loses the ability to separate the jaws, and hence cannot chew. Disability to consume solid food will, and often does, lead to serious impairment of the general health.

This form of ankylosis may be double, though, as a rule, it is unilateral. The ascertainment of the side which is ankylosed may prove difficult, and occasionally nothing short of a bloody exploration will decide the question. Severing of the bony union, with subsequent removal of the condyloid process by means of osteotomy, has been found to be an efficient way of removing this serious functional disability, and the method described by König[1] has been found by the author serviceable and safe.

An incision, beginning in front of the ear, is carried forward two and a half inches along the lower margin of the zygoma, care being taken to preserve the temporal artery intact. A second incision, involving the skin only, extends two inches downward from the middle of the horizontal incision. The soft parts are raised with the elevator from the bone, but occasionally very adherent periosteum has to be severed with a touch of the knife. The parotid gland and the facial nerve and vessels are displaced downward by means of a strong sharp retractor, and then the circumference of the condyloid process is stripped of its periosteum with a narrow elevator, care being taken not to injure the subjacent internal maxillary artery. The neck of the condyloid process is divided by the osteotome about half an inch below the joint. The jaws are pried open, and the remnants of the head and neck of the condyloid process are removed by the chisel and mallet from their temporal attachment. To avoid penetration of the cranium, the chisel should be directed downward and inward. The small wound is drained with a tube and closed by the requisite number of stitches, and an antiseptic dressing is applied in the usual manner. If no complications arise, the drainage-tube can be withdrawn on the third or fourth day, and the day after this, active use of the new joint should be commenced and diligently maintained, to prevent reankylosing.

---

3. *Rachitic Deformities.*—(*a*) *Knock-Knee.*—Genu valgum, one of the most common, painful, and disabling deformities of the locomotor apparatus, is, even in its more advanced forms, eminently amenable to successful treatment by osteotomy where osteoclasis would be deemed hazardous and orthopædic treatment futile. As it was known that the characteristic malposition of the tibia in knock-knee is caused mainly by the elongation of the internal condyle, it was natural that as soon as the safety of osteotomy was sufficiently established, this part of the femur should become the object of surgical attack.

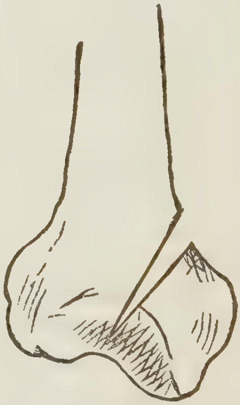
Fig. 14.



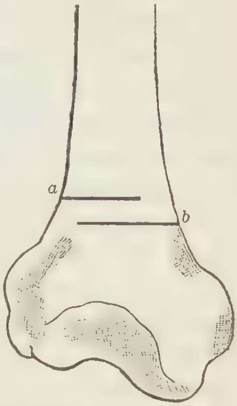
Macewen.

Older methods of osteotomy for knock-knee. (Poore.)

All the older methods, devised by Ogston, Reeves, Chiene, and Macewen, had the great drawback of saddling a simple osteotomy with the serious complication of invading the knee-joint, and all of them have been superseded in professional favor by MacCormac's and Macewen's methods of supracondyloid osteotomy (Fig. 15).

Macewen's Operation.—The limb, being carefully disinfected and rendered bloodless by Esmarch's band, is placed upon a sand-bag, where it is immovably held by the hands of two assistants. The detail of the procedure is thus described by the author of the method: "A sharp-pointed scalpel is introduced at a point where the two following lines meet,—one drawn transversely a finger's breadth above the superior tip of the external condyle, and a longitudinal one drawn half an inch in front of the adductor magnus tendon. The scalpel here penetrates at once to the bone, and a longitudinal incision is made sufficient to admit the largest osteotome and the finger, if the operator desires it. Before withdrawing the scalpel the largest osteotome is slipped by its side until it reaches the bone. The scalpel is withdrawn, and the osteotome, which was introduced longitudinally, is now turned transversely in the direction required for the osseous incision. In turning the osteotome, too much pressure must not be exerted, lest the periosteum be scraped off. It is then convenient to pass the edge of the osteotome over the bone until it reaches the posterior internal border, when the entire cutting edge of the osteotome is applied, and the instrument is made to penetrate from behind forward and towards the outer side. After completing the incision in that direction, the osteotome is made to traverse the inner side of the bone, cutting it as it proceeds, until it has divided the uppermost part of the internal border, when it is directed from before backward, towards the outer posterior angle of the femur. In cutting on these lines there is no fear of injuring the femoral."

FIG. 15.



a, MacCormac's line; *b*, Macewen's line.

When the bone has been sufficiently divided,—that is, about two-thirds or three-fourths of its thickness,—the remainder of the cortical substance is snapped by an inward bending of the limb.

Eugene Hahn, of Berlin,[1] reports excellent results from a combination of MacCormac's and Macewen's incisions. (See Fig. 15.) He says, and with much justice, that simple osteotomy, as practised by Macewen or MacCormac, is a very tedious operation in cases where the bone to be divided is very hard or very thick, or both, and that a great deal of time is saved by attacking the condyle successively from both the external and internal sides. Then the osteotome need not be sunk to a great depth, as each section need not penetrate more than about one-third of the thickness of the bone, and the whole operation, though somewhat more complicated, is nevertheless much shorter, and it seems also safer, than the original procedure of Macewen.

---

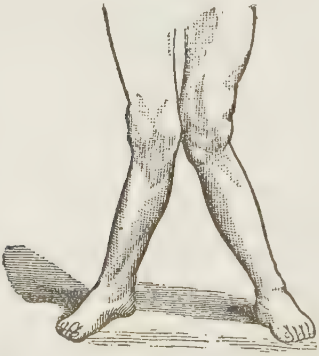
[1] Centralblatt für Chirurgie, No. 48, 1888.

The little wound is temporarily protected by a wrapping made of a towel dipped in an antiseptic solution, until the other limb, if need be, is operated on. In extreme cases, division of the tendon of the biceps muscle may be required, to enable the surgeon to accomplish a perfect straightening of the limb. On account of the vicinity of the outer popliteal nerve, the tenotome ought to be introduced between the skin and the tendon, and the division of the tendon must be done *from without inward*, or, better yet, open tenotomy is performed.

The wound is now enveloped in a not too bulky antiseptic dressing, the Esmarch bandage is removed, and the entire limb is enclosed in a well-padded plaster-of-Paris splint, an assistant maintaining meanwhile extension in the corrected position until the plaster has set. In the absence of plaster, a dorsal T-splint or a solid veneer and starched bandage splint will answer the purpose just as well. Before leaving the patient, care must be taken to ascertain that the circulation of the limb is unimpeded. The normal color and sensation of the toes may be accepted as a test. If the splint be not too tight, an opiate will be needed only for the first night after the operation.

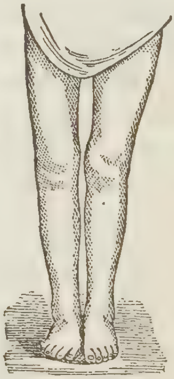
Should the rectal temperature rise beyond 101° F. during the first two nights, a careful physical examination must be made to ascertain the cause. Frequently a sore throat, pneumonia, or some other constitutional disturbance will be found to have caused fever. If the examination yield a negative result, and especially if severe pain be complained of at the site of the operation, some local disturbance within the wound or in its vicinity will have to be searched for, after the removal of the splint and dressing. Too much constriction, or else infection, will be found, and will require adequate treatment. The appearance of a slight blood-stain on the surface of the splint does not require its renewal. Dusting of the stain with iodoform powder, with exposure to the air, to hasten its drying, is all that is necessary.

Fig. 16.



Case of genu valgum, moderate deformity. (From Macewen.)

Fig. 17.



The same, after osteotomy. (From Macewen.)

If there is no pain, no fever, and no excessive staining by bloody effusion, the splint is not disturbed till the end of a fortnight, when it is removed, and in most cases the wound will be found nearly or completely healed.

After the removal of the first, a second splint is applied, and kept on until firm osseous consolidation is found to be complete. This may be expected in from three to six weeks from the date of the operation, according to the age of the patient. When the splints are removed, the patient should be encouraged to exercise his limbs in bed in the recumbent posture. When the joints have somewhat recovered their normal limberness, the patient is permitted to rise and to exercise with the aid of crutches. About ten weeks will elapse from the time of the operation until the full use of the limbs is recovered.

(*b*) *Bow-Leg.*—We have seen in the preceding section how in knock-knee the exact knowledge of the essential alteration of the outline of the internal femoral condyle has enabled the surgeon to direct his attack with great precision against the part needing correction.

In genu varum matters are very different. The deformity, instead of being dependent upon the morbid change of one well-defined locality, is distributed over a wider area. Instead of a simple lesion, consisting of the elongation of the internal condyle of the femur, we find here a more or less uniform outward curvature of one or two or all of the bones of the lower extremity, the greatest convexity being generally located about the knee.

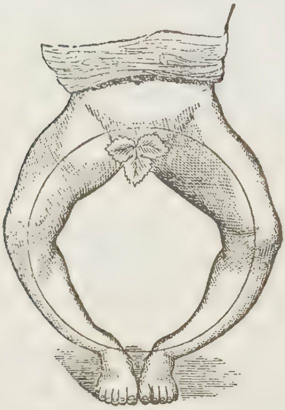
Though the deformity as a whole is very apparent, the precise fixation of the site of the greatest curvature is by no means easy; hence the selection of the place where osteotomy can be done most advantageously is likewise somewhat difficult.

On careful examination, either the uppermost portion of the tibial diaphysis, or the external femoral condyle, sometimes the lower third of the tibia and fibula, or finally the middle of the shaft of the thigh, will be found deviating from the normal outline. In extreme cases two or three or even all of these elements may be present, as in Macewen's case reproduced in Fig. 18.

Accordingly, it is evident that in the graver forms of genu varum one osteotomy will rarely suffice to bring about perfect correction, and that the number of the divisions of the bone will have to be in direct proportion to the number of the single elements of the curvature. In the case shown in Fig. 18 Macewen performed ten osteotomies at one time, with an excellent result, illustrated in Fig. 19.

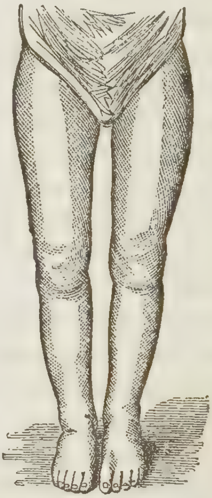
Regarding the technical management of osteotomy for genu varum the following rules may be laid down. Curvatures of the shaft of the femur are to be attacked from the outside of the limb. The cortical substance of the thigh is here very hard, and much patience will be required to accomplish division. If the outer condyle of the femur needs division, it will be best to perform Macewen's typical supracondyloid osteotomy *from the inner aspect* of the thigh, this being the easiest and safest procedure.

FIG. 18.



Aggravated case of genu varum.
(From Macewen.)

FIG. 19.



The same. Result after osteotomy.
(From Macewen.)

Tibial division consists of the following steps. On the inner surface, midway between the anterior and posterior borders, and at the height of the lower edge of the tuberosity of the tibia, a longitudinal incision an inch or two in length is made through the soft parts to the bone. The osteotome being introduced in the well-known manner, the bone is divided from within outward and from behind forward. The densest bone will be encountered in the neighborhood of the tuberosity. Frequently the fibula can be snapped and requires no division by osteotomy. Should osteotomy be necessary, an osteotome has to be used of a diameter less than that of the fibula, to avoid injury to the soft parts. The lower the tibia is divided, the harder the bone will be found to be.

The dressings and after-treatment in osteotomy for genu varum are identical with those in genu valgum.

Knock-knee and bow-leg sometimes occur combined in the same individual, and each affection will have to be treated according to its proper indication.

(*c*) *Anterior Tibial Curvatures.*—These curvatures either involve the entire length of the tibia, when the tendo Achillis is found to serve as a string to the bow formed by the shin-bone, or are confined to the lower two-thirds of the bone, or to the lower third alone.

In the milder forms of the disorder, simple osteotomy of the most projecting part of the bone from before backward will be found adequate for the correction of the deformity. In direct proportion to the gravity of the aberration, two or more simple osteotomies may become necessary, or, better still, cuneiform excision of the most prominent part of the curvature will have to be performed.

As a matter of course, rigid and efficient rules of asepticism form an absolute condition of these operations.

Cuneiform excision for anterior curvatures of the tibia is done as follows. Esmarch's bandage being applied, the fibula receives the first attention. If it appears from the age of the child or the hardness of the bone that simple snapping without osteotomy is not feasible, the fibula must first be divided by the osteotome.

The incision over the tibia is next made with the scalpel, penetrating to the bone, and of sufficient length to enable the surgeon to expose freely the area to be excised. A second, transverse incision is carried midway through the longitudinal slit in the periosteum, and the four periosteal flaps formed by the crucial cut are raised by the elevator and held aside with sharp retractors. Previous to all this the size of the wedge to be removed should be determined, by those who do not trust to their sense of symmetry alone as governed by the eye. The limb is laid on a sheet of card-board and the anterior outline of the tibia is traced thereon with a pencil. Then, parallel to this, another line is drawn at a distance corresponding to about the antero-posterior width of the tibia at the point of section. This pattern is now cut out, and will represent a rough lateral view of the curved bone. If this pattern is cut across at the point of greatest curvature, and straightened, the upper and lower segments will overlap, and the size of this overlapping triangle will give an adequate idea of the size of the wedge to be removed.

Let us return to the operation. The extent of the base of the wedge is marked off by two parallel transverse grooves, made with the chisel and mallet,—not the osteotome, but a chisel with bevelled edge,—and after this the wedge is taken away by a series of workmanlike chippings, with the exception of the hindmost remnant of its apex, which is snapped off. Some surgeons advise the removal of Esmarch's bandage at this stage of the operation ; but it must be remarked that this leads to great and unnecessary loss of blood, a serious matter in children. It is safer to tie those vessels the cut lumina of which can be recognized by sight, and this will be facilitated by gentle compression and kneading of the vicinity of the wound, which will mark the location of even the smaller vessels by the escape of a drop or so of blood. The tendo Achillis is always to be divided by tenotomy.

After thorough irrigation, the segments of the tibia are brought together, a drainage-tube is inserted into the lower angle of the cutaneous incision, the wound is stitched up with catgut, and an aseptic dressing is snugly applied to the limb, including the foot and the knee-joint. Coaptation of the severed tibia is secured by a carefully-applied plaster-of-Paris splint. The drainage-tube should be left long, so as to project somewhat over the plaster cast. When the plaster has hardened sufficiently, but while it is still moist, an ample fenestra is cut out around the drainage-tube, until the aseptic gauze dressing is exposed to view. Then the tube is cut off short, transfixed with a pin, and its end well enveloped in a generous bunch of iodoform gauze, which is snugly bandaged down to the splint, so as to exercise adequate pressure upon the underlying tissues for the prevention of local œdema.

The limb is now elevated, and, Esmarch's band being removed, digital compression of the femoral artery over the ramus of the os pubis is practised for five or ten minutes, or until the hyperæmia caused by the vaso-motor paresis has disappeared. At first the toes become deeply flushed; as soon as this flush has given way to the normal pink color of the skin of the toes, compression of the femoral artery may be relinquished. An elevated position of the limb, however, should be maintained for an hour or two afterwards.

If the course of the healing be normal, which will be manifest by the absence of septic fever and local pain, the drainage-tube can be exposed and withdrawn on the third day after the operation, and this can be done without disturbing the deeper dressings. The fenestra is filled up with a mass of iodoform gauze as before, and the dressings are not interfered with till after a fortnight, when the plaster splint is removed, the limb is redressed, and another splint is applied, to remain *in situ* until the time of presumable consolidation has arrived.

Should septic fever, with much sickness and dejection, chills, and unusual local pain, point to an infection of the wound, a sufficient quantity of the dressing should be forthwith removed from the fenestra to expose it and to enable the surgeon to form an idea of its condition. The removal of a few confining stitches will often be sufficient to reduce tension and to improve drainage. A moist dressing, covered with a suitable piece of rubber tissue, is to be applied to the wound, and is to be changed at least once a day till the discharges become sweet and scanty. The edges of the fenestra are to be lined with strips of adhesive plaster and coated with several layers of alcoholic shellac solution. But finally the plaster will become foul, and will have to be removed, when the limb is to be subjected to a thorough purification before a new dressing and plaster splint are applied.

(*d*) *Flat-foot.*—For the sake of completeness, it may be mentioned that in severe cases of pes valgus in adults,—a deformity universally accepted to be rachitic or quasi-rachitic,—where milder and ordinarily successful methods of treatment have proved ineffectual, cuneiform osteotomy of the tarsus has been performed with marked success. Without reference to the joints, a wedge, having its base on the inner margin of the planta and its apex on the outer margin of the dorsum, is removed from the foot by means of the chisel and mallet, until an approach to the normal arch of the foot can be brought about, and maintained by the apposition of the cut surfaces. The size of the wedge is proportioned by the degree of deformity to be corrected. The wound is to be managed as in other cases of cuneiform osteotomy. Usually ankylosis of the opposite bony surfaces and a marked functional result can be achieved. This operation is rarely, if ever, indicated in pes valgus of children, and hence need not be treated in this volume to such an extent as its importance otherwise would demand.

Tarso-osteotomy, simple or cuneiform, is occasionally required for the correction of aggravated and rebellious forms of another, though non-rachitic, deformity,—namely, *club-foot.* But as this subject has received adequate treatment elsewhere in this volume, it may suffice to say that, in conformity with the nature of the trouble, the base and apex of the wedge to be removed occupy exactly opposite relations to those in the operation for pes valgus. That is, in club-foot the base of the wedge is to be where the apex is in splay-foot, and *vice versa.*

MECHANICAL TREATMENT OF DEFORMITIES OF INFANTILE PARALYSIS.

BY E. G. BRACKETT, M.D.

THE mechanical treatment of deformities arising from infantile paralysis, irrespective of the part of the body affected, is to be guided by the time the affection has existed, the amount of impairment of muscular power, and the degree of deformity which has occurred. On this basis of treatment the cases may be divided into three classes :

1. Those in which the treatment is directed only to the prevention of deformity.

2. Those in which deformity has occurred, but in which this deformity can be overcome by a reasonable amount of force.

3. Those in which surgical aid is necessary to overcome the existing distortion.

The deformities accompanying this affection are mostly, if not entirely, the result of mechanical forces, and occur slowly with the growth of the patient. The deformity is usually maintained by the adaptability of the muscles to the positions which are allowed to be assumed, as has been shown by Volkmann, and the structures, therefore, which oppose the reduction of the deformity are the muscles and the ligaments.

A great majority of cases are not brought to the surgeon for treatment until considerable atrophy and deformity have taken place, but inasmuch as these distortions occur after a time when a perfect development has begun or been attained, the deformity is but little dependent on bony change, except in severe cases of long standing where a considerable growth has occurred during the existence of the deformity. Therefore, when the part is held by these contracted structures, mechanical treatment must often be preceded by division of the opposing structures, unless the part can be brought into its proper position by ordinary manipulation.

Since the essential cause of these deformities is the lack of power of certain muscles or groups of muscles, this etiological factor must be borne constantly in mind in the course of correction, in this respect differing from the congenital cases, in which the muscular structures are nearly or quite perfect, and after correction may be of service in maintaining a normal position.

The length of time that it is necessary to continue treatment will depend on the degree of paralysis and on the age of the deformity, but, in general, when there is considerable weakness the foot must receive attention until the period of growth has been passed, or later if any tendency to deformity is then manifested.

The most important class of deformities from this cause demanding treatment are those of the foot. Considered in this paper are pes equinus, pes varus, pes valgus, and pes calcaneus, as well as deformities of the knee, the hip, the back, and the upper extremity.

Pes Equinus.—Of this variety of distortion there are two principal characters, which are found singly or combined, and consist of a flexion of the whole foot at the ankle-joint, or of the tarsus on itself. Of the former, particularly, all degrees are met with, from a right-angle contraction, to a condition in which the dorsum of the foot forms a continuous line with the leg, and in severe cases the toes may be directed backward and locomotion take place on the dorsum. In the other class the posterior part of the foot may be in nearly a normal relation with the leg, although the motion in the ankle-joint is much restricted, but the foot presents a more or less sharp curve opposite the arch, caused by a flexion at the medio-tarsal or tarso-metatarsal joint. This deformity is much more noticeable on the inner than on the outer border.

The relation of these to a very slight deformity caused by a contracted condition of the fascia has been shown by Fischer,[1] and they have been called by him talipes arcuatus and talipes plantaris. He considers them to be due to early transitory paralysis, perhaps not infantile, after which the growth of the fascia was not proportionate to that of the rest of the foot. They are essentially the same as the affection described by Shaffer as non-deforming club-foot.

The advisability of any treatment in slight degrees of simple equinus showing no tendency to increase, and accompanied by shortening of the leg, should always be considered. It compensates the loss in length, is not more unsightly than a high sole, and allows a more natural use of the foot and leg, which must result after the period of growth in a better development of the limb.

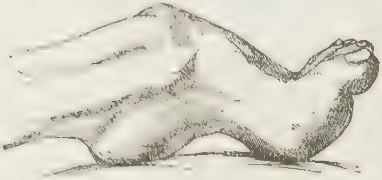
Whenever the contraction of the tendo Achillis prevents the forcible restoration of the foot to a right angle, it is doubtful if it is wise to attempt the reduction of the deformity by mechanical means alone, unless the condition has existed for but a short time. The risks from tenotomy are so slight, and the accomplishment of the object is so thorough, that it must be given the choice except in occasional instances; while the use of apparatus requires the expenditure of much time and patience for the accomplishment of but little.

But in cases requiring interference other parts of the foot need attention, and particularly the sole, when there is deformity situated in the middle of the foot. In extreme cases, where the foot forms nearly a continuous line with the leg, division of the deep flexor tendons may be necessary, but should not be done until forcible straightening has been tried, as the amount of shortening which accompanies this depression of the anterior part of the foot is very slight, and the deformity usually yields remarkably in this direction. As an example of this is shown Fig. 1.[1] The foot in this case yielded to the Thomas wrench, and division of the tendo Achillis only was necessary. But when there is sufficient contraction of the plantar fascia to prevent the foot from being brought into a normal position by ordinary force, division or replacement by forcible correction is advisable. Osteotomy in these cases of paralytic deformity must be considered as an operation rarely necessary. Very many would yield to the slow process of gradual replacement by repeated application of stiff bandages, but the method is not sufficiently advisable to be more than mentioned, and the remarks in reference to forcible straightening apply only to the surgical treatment which may be necessary before the mechanical can be begun.

---

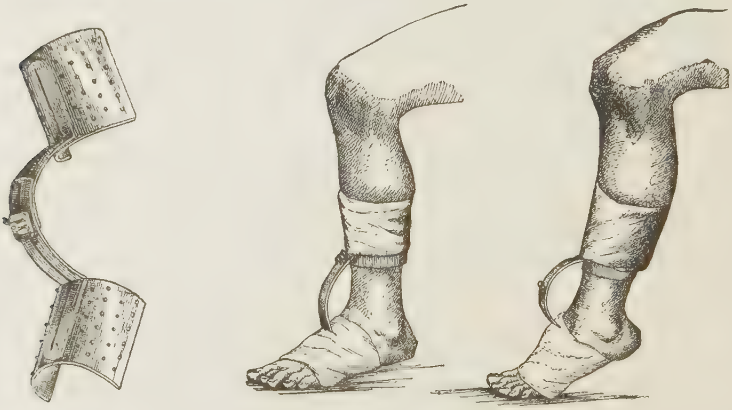
[1] Lancet, January 26, 1889, *et seq.*

Fig. 1.



Among the appliances for forcible correction by gradual reduction is that of Stillman, shown, with the manner of applying it, in Fig. 2. After the proper position has been obtained, retentive apparatus will be necessary, as after correction by other means.

Fig. 2.



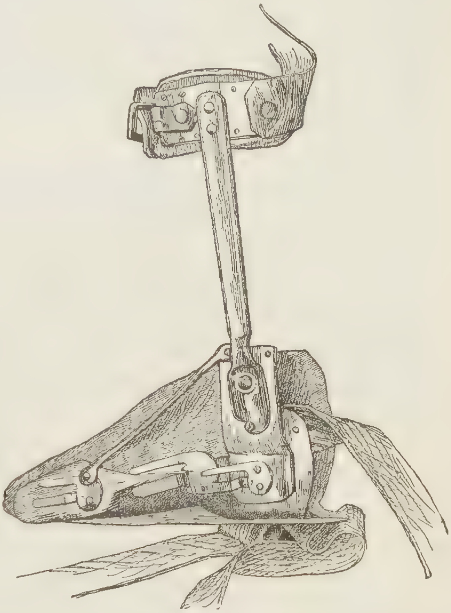
Mechanical treatment after operation consists purely in the retention of the foot in as nearly a normal position as surgical treatment will enable it to be brought: in fact, mechanical treatment in all of these cases may be considered as beginning where surgical treatment ends. The tendency of the foot when left to itself must be borne in mind, and the apparatus applied with the aim of preventing this, and, if this is successful, we may be confident that no permanent deformity will occur.

---

[1] Used by permission of Dr. H. L. Burrell.

For most cases of this class, as well as of varus, the best form of retentive apparatus is the Taylor club-foot shoe, which possesses the advantage of being easily applied, and, as it can be worn inside an ordinary boot, is not unsightly. This well-known appliance (Fig. 3) scarcely needs description, but a few of the important particulars of its application in these deformities may be briefly noticed. The sole-plate should extend from the extremity of the heel to the cleft of the toes, following more or less closely the contour of the outer border of the foot. The upright should extend on the inner side of the leg nearly to the knee, and be there secured by a strap passing round the calf. Extension at the ankle is checked at any desired point by the stop-joint, and this usually is at a right angle. In applying this shoe the foot should first be strapped to the sole-plate, with the upright bent forward, and this must not be brought into position on the leg until the foot has been secured. This is especially important with the varus deformities.

FIG. 3.



When the deformity is that of a flexion at the ankle-joint, it is necessary that the heel should always be in contact with the bottom of the shoe. When the foot presents the angle at the arch, it is important to keep the anterior part of the foot on its normal level. This must be done by pressing the centre of the foot firmly down to the plate while securing the straps.

For the slight degrees of deformity designated by Fischer as talipes arcuatus and talipes plantaris, treatment is purely the correction of the deformity which is kept up by the contracted fascia, and which may be overcome either by surgical or by mechanical means. After correction mechanical appliance is rarely necessary, as the muscles have usually so far regained their strength that the deformity does not recur. The foot should be watched, however, for such tendency, and treated if necessary.

The same object may be accomplished by mechanical means by repeated application of the plaster bandage with this contracted fascia on the stretch. Among the advantages which this method possesses, the rest which is necessitated is an important one. There is frequently little or no diminution in the size of the muscles, but the foot becomes tired much more easily than its fellow, and at such times a limp is frequently developed, apparently due to the tension of the muscles which is necessitated by the condition of the foot. Shaffer advises the gradual reduction by the use of the extension shoe.[1] Its full description would demand too much space for this article, but its construction is based on the principle of imitating the natural centres and directions of motion of different parts of the foot, and the force applied is that of traction. It is intended for any form of equinus, but the method of its employment in the non-deforming club-foot differs somewhat from that in ordinary equinus. Complete description will be found in the article to which reference is given.

Many other forms of appliance have been devised and are still used, but preference has been given to the Taylor shoe, as it is both easy of application and efficient. The elastic muscles of Barwell have had extensive use, but have never found much favor here. If they are stiff enough to overcome the deformity and hold the part in place, they accomplish no more than unyielding apparatus which can be accurately regulated. The idea of substituting elastic tension in place of the weakened muscles was carried to a high degree of perfection by Duchenne, who not only used delicate springs for separate muscles, but also imitated their insertion-points. It is doubtful if this elaborateness has any practical value, and the plan followed by Barwell in so placing this elastic extension as to bring the foot into the desired position without reference to the insertion of the natural muscles is better. The artificial muscles are secured to the limb by means of adhesive plaster. The special forms which are used for the different types will not be here enumerated, but they are such as to imitate the direction of the force used by the hand in correcting the abnormal position.

The importance of wearing a support at night in the equinus as well as in the equino-varus deformity should not be overlooked. The pressure of the bedclothes is in a direction to maintain and to exaggerate the tendency to deformity, and this influence is undoubtedly an important etiological factor in many of the slightest cases. It is by no means necessary that the walking appliance should be worn, but any form which will prevent the foot from being pressed into its unnatural position will be sufficient. For both the pure equinus and the equino-varus the same apparatus will be useful. A posterior wire splint, consisting of a long narrow frame wide enough to support the leg comfortably, extending from the upper third of the calf to the end of the toes, and bent to a right angle at the heel, is an efficient appliance. A covering is stretched between the wires, and the foot is strapped or bandaged to the frame.

This same principle is carried out by supports made from tin or wood, which are equally efficient, but more cumbersome.

---

[1] New York Medical Journal, March 5 and 12, 1887.

Pes Varus.—Usually this form is associated, as are the congenital forms, with equinus, but it may occur independently; and existing in a slight degree, shown only by a dropping of the anterior part of the foot and a slight inversion of the toes when the foot is hanging and at rest, this forms a common condition. But this position in time tends to become permanent by the contraction of the plantar fascia with the shortening of the muscles, and an equino-varus results.

As the distortion increases, the ball of the foot approaches the heel at the same time with the rotation of the fore part of the foot, and, as this inversion occurs principally at the medio-tarsal articulation, the locomotion is chiefly on the fourth and fifth toes and the ends of their metatarsal bones. It is evident that from this a severe distortion may occur by a further increase in the same direction.

One form of varus, due principally to weakness of the peronei, often is seen, in which there is little or no tendency to permanent deformity, except a slight eversion of the foot at the ankle-joint. The foot can be thrown forward so as to bring the foot to the ground, but without this effort the foot, which when at rest hangs loosely with the toes pointing almost directly downward, first comes to the ground on the anterior part of the outer border, and, as the weight of the body is thrown on the leg, is rolled over, so that the weight is borne entirely on the dorsum. This happens when the patient walks quickly or carelessly, but when attention is given the foot can be placed flat on the ground. In this way the abnormal position does not become habitual, and contraction with permanent deformity does not occur; but as the foot is used, this malposition is assumed more and more, until it may become usual during the act of walking.

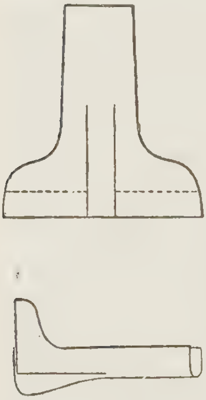
The varus element rarely requires more than mechanical treatment, unless the deformity has existed so long, and the inversion of the toe and of the whole foot has been so severe, that contraction has occurred, in which case either division or forcible correction would be indicated. Probably most cases would yield to the slow stretching process; but this requires an unnecessary amount of work and patience on the part of both surgeon and patient, and much loss of time. If, however, the deformity yields to forcible manipulation, correction by mechanical means may be undertaken.

In restoring the position of the foot, whether by operation or by mechanical measures, the inversion of the fore part of the foot should first be corrected, next the rotation, and finally the equinus. If operative measures are necessary, the choice of method must be decided by the individual case, but two surgical aids to a successful or at least a speedy mechanical treatment are commonly valuable,—section of the plantar fascia and section of the tendo Achillis. More resistance is given by these two structures than by any other which it is necessary to overcome, and it is not wise to spend too much time in a slow stretching process.

Shaffer strongly recommends the use of the lateral traction shoe, which embodies the same principles as the traction shoe, but is applied to the varus deformities. By this the foot can be gradually forced into position, and this force applied in whichever direction and in whatever amount may be found necessary at different stages of the correction.

For retention after the deformity has been overcome, and for cases where no distortion has occurred, the Taylor club-foot shoe will be found adapted in the majority of instances. If equinus is associated with the varus, a stop-joint at the ankle will usually be necessary, so placed as to prevent plantar flexion beyond a right angle. It is of great importance that the shoe be correctly applied, as otherwise the foot will not be brought into proper position, and the apparatus will be ineffectual. The foot must be pressed firmly against the sole-plate, with the upright brought forward, lying obliquely across the leg. The foot is then secured by the straps, and finally the upright is forced back into position. By this motion the varus and equinus are corrected. Applied in this way it acts both as a correcting and as a retention appliance. Occasionally, when there is shortening of the leg, this stop may be omitted, as the slight amount of equinus compensates this, improves rather than injures the gait, and adds to the comfort of the patient. When there is but a slight inversion of the toes, the apparatus may be made very light, with a simple joint at the ankle; and the same is true when this is associated with a moderate degree of rotation of the fore part of the foot.

Fig. 4.

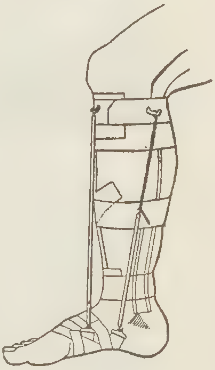


In many of these cases of slight degrees of deformity it is a question to be carefully considered whether any apparatus should be worn during the day; but the importance of some support at night cannot be too strongly urged, and the recurrence after correction in many cases and the persistency in others are often undoubtedly due to the pressure of the bedclothes against these weakened muscles. Frequently support during the day may be dispensed with when the foot is not brought into an abnormal position while bearing the weight of the body, and the natural use of the healthy portion is then not restricted by the apparatus. The form of the appliance worn at night is not important, so long as the foot is kept in position. The wire splint can be used, or a tin shoe, which can easily be made by any one. A piece of tin is cut into shape and bent and riveted in the manner shown in Fig. 4. The dotted line indicates the part which is bent inward to make the sole. The upper portion is curved to fit the calf, and the small tongue is turned backward to remove the bearing from the heel. It is important to have this concavity deep enough to hold the heel without pressure.

Pes Valgus.—When this exists to a slight degree, forming a flat foot only, with no other distortion of the foot, rarely will more than an adequate support to the arch be required. The eversion of the foot is consequent to the giving way of the arch, and the position of the foot closely resembles that in the so-called static flat-foot. This deformity existing alone is usually slight, being due to slight weakness and seldom seen until long after the original trouble; but it is by no means always due to this cause. When the arch is maintained in its normal condition, sufficient correction is obtained. The most practical form for this support is the plate devised by Dr. Whitman for flat-foot, which gives an efficient support to the foot, and interferes to a slight extent only with the movement of the articulations of the tarsus. This is fully described in the article on club-foot, and needs no further reference here.

Elastic extension has been used with this as with the other forms, among which is the ingenious contrivance of Barwell, the principle of which is shown in Fig. 5. The arch is supported by means of the webbing which is wound around the foot and secured above, with the intervention of elastic bands. The force, however, which can be borne as a constant pressure is so far exceeded by the amount necessary to hold the foot while in use that it cannot be uniformly serviceable.

FIG. 5.



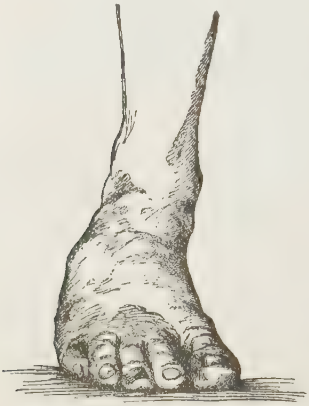
The more commonly seen deformity of this class is a condition in which, added to the giving way of the arch, there is a marked eversion of the whole foot at the ankle-joint. The inner malleolus is abnormally prominent, and in proportion to the amount of eversion is made to approach the ground by the superincumbent weight. When at rest, this deformity frequently nearly disappears, but with the foot hanging the toes are found to droop more than on the well side. The deformity is an unfortunate one, as the use of the limb strongly tends to increase the distortion. Associated with this there is often considerable weakness of the peronei, and in walking the toe drags and is turned outward.

The object in the mechanical treatment of this deformity is both to support the arch of the foot and to prevent the eversion at the ankle-joint. In many cases a well-adjusted support to the arch is sufficient, this preventing the eversion of the foot, but a simple plate is not enough. The object may be accomplished by a band of leather secured to the inner surface of the shoe along its outer border, passing beneath the arch of the foot to above the outer malleolus, where it is fastened to a short upright connected with the shoe.

An effectual apparatus is made by combining the plate used by Whitman with an outside upright provided with an ankle-joint and connected with a plate fitting the outer border of the foot. To this piece the sole part is firmly attached by leather, which covers the inner side of both, and is continued up over the dorsum of the foot, from the inner side, by straps which buckle to the upright and to the plate. This possesses the advantage of a firm support at the weakest part, and this support is moulded to the form of the foot.

When the eversion of the foot predominates, and particularly if there is but little displacement of the arch, as is shown in Fig. 6, the sole-plates are of no benefit. In these the most commonly used appliance consists of an upright on the outer side of the leg, fastened to the sole of the boot, and extending to the upper third of the calf, with a joint at the ankle. A triangular piece of leather is secured to the boot and to the upright, so that its centre is over the inner malleolus, with one point attached to the sole of the boot near the inner edge, and the other two connected with the upright by straps, one passing behind and the other in front of the ankle. As the tendency is to a lateral displacement inward of the ankle-joint when the weight is borne on the leg, this arrangement sufficiently prevents this movement, and when the leg is free from weight the deformity is so much less that the straps are not tight enough to cause discomfort.

FIG. 6.



The same principle of support is carried out more effectually by the Taylor club-foot shoe. This is essentially the same as the usual form which has been described, with the upright placed on the outer side. The inner edge of the sole-plate is made to conform to the shape of the inner border of the foot, or this plate may be arched to fit the natural arch. The foot is secured to the apparatus in the usual way, with straps and buckles.

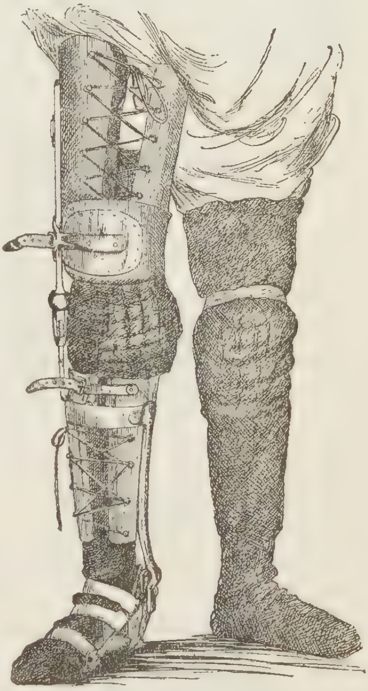
Pes Calcaneus.—This must rank among the rare deformities resulting from infantile paralysis. Cases of pes calcaneus are usually of a severe type, are accompanied by a very great loss of power, and come under observation only after a long lapse of time, during which there has generally been complete neglect. There is, then, in the majority of cases, when first seen, a decided valgus, so that the deformity should properly be called calcaneo-valgus.

The benefit to be derived from mechanical treatment alone in the severe cases is in the direction of giving comfort to the patient rather than of improving the condition of the foot. Surgical measures can diminish the deformity, but firm retention is then necessary. For this the Taylor outside shoe, with a stop-joint to prevent extension beyond a right angle, is an efficient means. In the simple cases in which the deformity is that of calcaneus alone, this will be found sufficient, but in the severer forms it will be found better to mould the sole-plate to correct the valgus. The combination of the Whitman plate and the outside upright will meet the requirements in most cases.

Knee.—The deformities of the knee which require treatment are chiefly a condition of hyperextension and one of permanent flexion. These, and particularly the former, are the result of a very marked paralysis of the leg while the thigh is but little affected, or of a very general paralysis of the whole leg. The treatment of these two conditions is essentially different, and the latter will be considered later. As the muscles which control the hip-joint are essentially normal, support may be had from the thigh. As in this class of cases the weight cannot be supported when the knee is bent, the leg is thrown into full extension before the foot is put to the ground, and this position is assumed with each step in walking.

For this simple hyperextension of the knee-joint, or for cases in which the loss of power is chiefly below the knee, without any deformity, the caliper-splint forms a simple means of support. A steel wire passes on either side of the leg and beneath the foot, when it goes through a socket which is secured to the shoe. The inner wire should extend nearly to the perineum, the outer a little higher, and these two are connected by a plate which passes behind the leg and by a broad strap in front. A leather band secured by the four corners and passing behind the knee will prevent the hyperextension, and a pad over the knee is usually necessary. As a rule, further retention is not required, but, when necessary, may be applied to individual cases.

Fig. 7.



Another form, less cumbersome, but scarcely more efficient, is shown in Fig. 7. It consists of an outside support jointed at the knee, with anterior and posterior plates to hold the leg in the position required. It possesses the advantage of allowing the patient to bend the knee while sitting, the joint being locked by the drop-catch when the patient stands with the leg extended. If with the affection of the knee there is associated a deformity of the foot, the splint may be connected with a club-foot shoe which is worn inside the boot; but otherwise it is better to connect the splint with the shoe and with a simple joint at the ankle.

A very ingenious splint has been used by Walsham[1] for cases with this distribution of the paralysis. Its object is to allow the thigh-muscles to control the motion of the leg. The apparatus consists of an outside upright jointed at the hip and the knee. By two additional strips connected with these two joints by levers, the motion of the leg can be governed. When the thigh is extended, the leg is held straight, and is not released until the thigh is flexed. The Walsham splint has the particular advantage of allowing motion at the knee during the act of walking.

---

[1] Lancet, July 28, 1888, p. 158.

When contraction at the knee exists, it is usually in those cases where the leg has had little or no use, and motion is free to a certain point, where it is arrested by the shortened hamstrings and the contracted capsule. By a slow process of gradual reduction or extension the contraction may be overcome; but surgical means attain this object with the loss of but little time. Retention is then accomplished as in the other cases.

Knock-Knee.—Two etiological factors have influence in the occurrence of this deformity in infantile paralysis,—the direct weakness of the muscles, and the positions which are assumed in the efforts to use the leg, when the paresis involves some other part than the knee, as the foot. When it is due purely to the latter, and no bone-malformation has resulted from long continuance, treatment directed to the foot only will be required for the correction of this part. When it results from weakness of muscles of the thigh or about the hip, and the position which is assumed in the effort to maintain equilibrium tends to develop this deformity, treatment must be directed to the impaired parts primarily. If bone-changes have taken place, they must be treated on the general principles of the correction of knock-knee.

Hip.—Deformity at the hip is perhaps always associated with paralysis involving the whole leg and when but little regeneration has taken place. It is caused by a contraction of the sartorius and the fascia of the thigh, which produces flexion at the hip-joint. The leg is small and flail-like. When the attempt is made to extend the thigh, it is arrested by a tense band which is seen extending downward from the anterior superior spine. When left to itself, the leg falls outward and then becomes flexed, so that the whole leg rests upon its outer surface. The knee-joint is usually lax and permits hyperextension, and the foot has a tendency to either varus or valgus deformity. The use of the limb may be practically lost, or the patient may retain considerable power in certain directions.

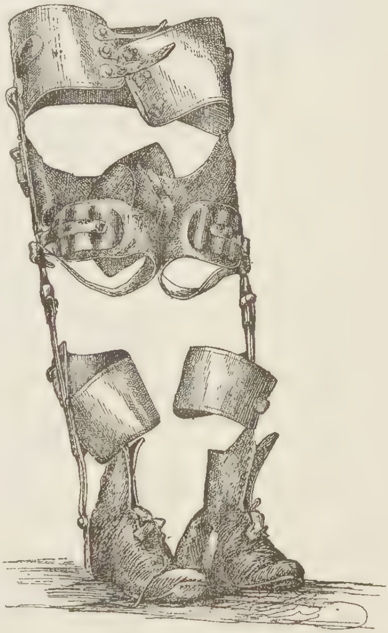
It is the amount and character of this control that must be considered in deciding what form of support is to be given. With judicious selection of apparatus a considerable improvement in the usefulness of the limb can be obtained, even in cases of long standing, when they can be had during the periods of growth, and by affording additional use of the limb we can expect the adult growth to be reached with less atrophy and shortening, which are undoubtedly more directly in proportion to the disuse than to any other cause. The early application of apparatus is directed more to the prevention than to the correction of deformity, but the form of support used does not differ essentially in either case.

The contraction at the hip requires operative interference if great enough to prevent the patient from standing erect with both feet flat on the ground. Division of the superficial structures in the anterior part of the thigh, either by subcutaneous section or by open incision, will usually accomplish this, although it will not entirely overcome the deformity. The contraction remaining is maintained by the deep structures, principally the tendon of the iliacus and psoas and the capsule, the division of which involves risk which would be justified by necessity only.

The most difficult cases to treat are those of paralysis involving both legs, with loss of power so great that the patient is unable to walk or stand alone. Rarely are both limbs paralyzed to an equal degree, certain movements being generally possible with one, so that it can be used to support the body when placed in the proper position, while the other is quite lax. Even those children who have never walked can, with the aid of properly-applied support to both legs and with crutches, be enabled to go about alone. Although their locomotion is slow and awkward, it is far preferable to the utter helplessness of the other condition.

Fig. 8 illustrates the form of apparatus which may be used in these cases. It consists of an upright attached to the sole of the boot and extending above the trochanter. When a double splint is used, it is best secured to the pelvis by a broad leather band encircling the waist and connected to it by either a simple hinge or a ball-and-socket joint; but when the splint is single, it is best secured by a steel band which nearly half encircles the pelvis. The knee-joint is provided with a stop, which keeps the leg extended while walking, but allows the knee to be bent while sitting. The thigh is firmly held by a posterior and an anterior plate, but the leg is sufficiently held by a calf-plate and a strap. When this apparatus is necessary for one leg alone, there is usually no need for additional aid by a crutch or cane. With double paralysis, crutches are almost essential, and progression may be in one of two ways: either the weight is borne on both crutches at once and both feet are swung forward, or one crutch is put forward and the foot on the opposite side is then swung or dragged forward, and the same movement is repeated by the other side. This manner of locomotion is usually practised when the paralysis is very extensive.

FIG. 8.



Spine.—Lateral curvature due to purely unequal action of muscles of the trunk is not of frequent occurrence, but as a result of inequality of the length of the leg it is very common. When this shortening is due to infantile paralysis, there is associated with it a loss of muscular power, which adds another influence to the distortion besides the simple disturbance of the normal plane of the pelvis.

As to the form of support in these cases, no special directions are required beyond those for the general treatment of lateral curvature, but some kind of appliance is necessary, at least during the growing period, to maintain, so far as possible, the normal shape of the trunk, since the weakness of the muscles is an ever-present influence towards a distortion. Perhaps the most thorough support is given by a close-fitting leather jacket moulded over a cast of the patient which was taken while he was as nearly as possible in the correct position.

Shoulder.—The principal deformity affecting the shoulder is caused by a paralysis of the deltoid particularly, which results in a kind of subluxation of the head of the humerus. In addition to the disability, this paralysis is unfortunate, as the unequal use of the arms and their weight tend to produce a dorsal curve; but, happily, it is rarely met with. The affection is hardly amenable to mechanical treatment, other than that of supporting the arm by firm bandages, but these all interfere very considerably with the use of the joint.

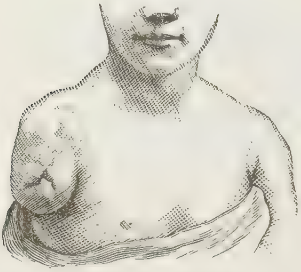
AMPUTATIONS.

By WILLIAM BARTON HOPKINS, M.D.

In considering the conditions which warrant the performance of amputation in children, and indicate this radical measure instead of some conservative operation, their constitutional peculiarities, their nutritive functions, the quality of their general vitality, and the activity of their local circulation and nutrition should be carefully compared with those of the adult. While physically they are more deeply affected by shock than adults, psychically they are far less susceptible. The dread of losing a limb, and with it possibly the means of obtaining a livelihood, which often is such a depressing factor in adults, and which, as every surgeon has observed, often retards reaction, does not obtain with children. I recall an incident strikingly illustrating this. A small boy in hospital cheerfully said to me, "Eddie was operated on to-day, and I am going to have my leg off to-morrow." Profoundly influenced by shock, children react quickly and often violently. Anæsthetics, which usually act particularly well in them, have to be given with great caution when they are suffering from shock. They feel the loss of blood relatively more than adults, and I incline to the belief that they are more susceptible to sepsis. Their processes of repair in an injured or a diseased part are very active, and their bones are soft and vascular. Fewer limbs need be amputated for injury in children, and much more extensively damaged tissue can be saved and utilized in them than in adults. Amputation, too, is much less frequently required for disease of the bones and joints in children, as in them excisions, resections, and other conservative means afford the best possible prospects of success.

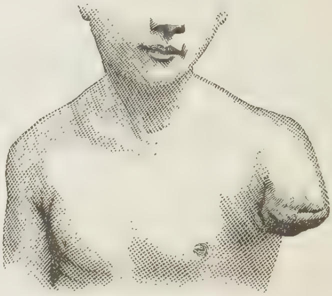
The changes in the skeleton which depend upon the growth and development of bone also have an important influence on amputations in certain regions. The most important of these is the activity of the growth of the epiphyses. In an adult the value of retaining the head of the humerus in an amputation at the shoulder-joint, for example, would hardly be considered, while in children the result following this conservatism fully warrants its being attempted. Figs. 1 and 2 represent two children operated upon by the writer, both thirteen years of age. In one, amputation was done at the shoulder-joint; in the other, the head of the bone was retained, along with a small portion of the shaft. At the time but little difference appeared between the two stumps; three and a half years later, however, the contrast, as shown in Figs. 3 and 4, had become very marked. The girl's shoulder-joint, Fig. 3, presents the wasted, helpless appearance which characterizes this stump, while the boy's shoulder, Fig. 4, is full and round, and he can help himself with it in numerous ways.

FIG. 1.



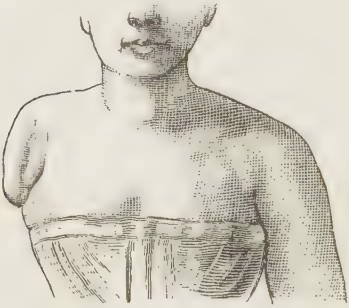
Stump after amputation at the shoulder-joint, in a girl of thirteen years.

FIG. 2.



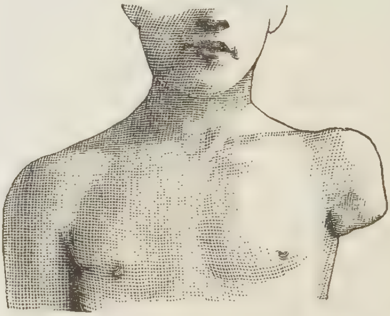
Stump after amputation, where the head of the humerus was retained in a boy thirteen years of age.

FIG. 3.



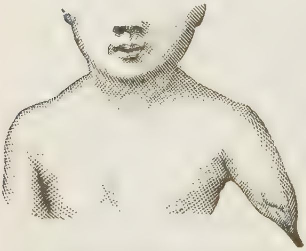
Condition of stump three and a half years after shoulder-joint amputation (see Fig. 1).

FIG. 4.



Stump three and a half years after amputation near the shoulder-joint, little more than the head of the bone having been retained (see Fig. 2).

FIG. 5.



Conical stump in a boy of about six years, three years after amputation of upper arm. The bone seemed to be covered only by a scab.

Epiphysial growth, while it may be made subservient to the function of a stump, very frequently, when the flaps have not been made sufficiently large to accommodate the increased size of the bone, may become a cause of mischief, producing the condition of conical, irritable stump, which requires re-amputation. Fig. 5 represents a stump of this kind, photographed from a boy at the Pennsylvania Hospital, three years after an upper-arm amputation. The bone in him projected, thinly covered with skin, very much in the form of a goose-quill. While it is not known how much the flaps sloughed after the amputation, the appearance of the stump strongly indicates that the humerus was thrust out by its growth, and not left exposed by the recession of sloughing flaps.

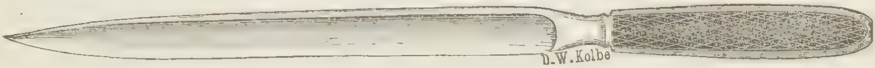
TECHNIQUE OF THE OPERATION.

The instruments and apparatus needed are very simple and few. They should be properly prepared and kept immersed in antiseptic fluid as in other operations.

An ordinary razor is required, to shave the hair from the limb at the site of amputation and to a considerable distance above it. It is better to shave off even the delicate growth of hair in children; done carefully with a keen-edged instrument, the risk of the skin being made thereby a medium for the absorption of septic matter is not to be considered.

For operations by transfixion a straight knife (Fig. 6), with a rather delicate blade, one-third longer than the diameter of the limb at the point of amputation, is the only knife needed, except a scalpel, unless the amputation is of the forearm or leg, when a catling of very moderate length is also required to divide the tissues between the bones. For flap operations where the tissues are to be divided from without inward a much shorter knife will do more rapid and certain work. For the fingers and toes a Neill's amputating knife, which is a cross between a scalpel and a straight bistoury, is very useful.

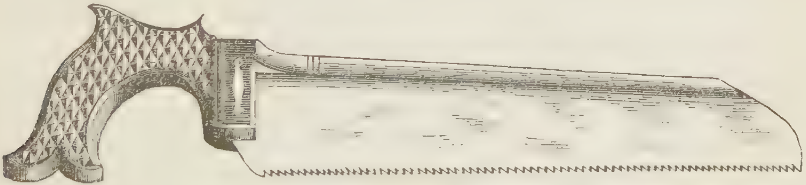
Fig. 6.



Long amputating knife.

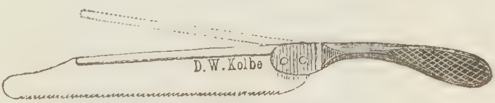
The surgeon should be supplied with an ample number of catch artery-forceps, certainly not less than a dozen for an ordinary amputation. A two-tailed retractor for a single bone, and a three-tailed retractor for a double bone, should be made of unbleached muslin carefully boiled and rendered aseptic. A saw (Fig. 7) very similar to that used in the carpenter's mitre-box is applicable for the division of all the larger bones; for the smaller bones a very delicate saw (Fig. 8), with a narrow spine to its blade, will usually be found to leave a nicer surface than when the division has been accomplished with bone-forceps. These (Fig. 9) should always be at hand, however, to cut off any little splinters or uneven edges of bone left by the saw.

Fig. 7.



Amputating saw.

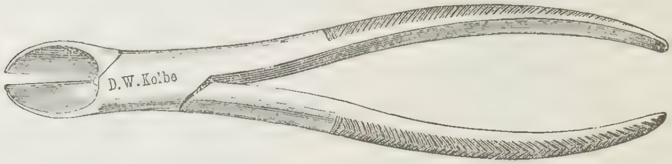
Fig. 8.



Saw for small bones.

Two or three long needles should be provided, in order that the approximation of the flaps may not be delayed while they are being threaded. The needle I prefer (Fig. 10) has a lance-shaped point. In introducing a needle and carrying through the material with which it is armed, two distinct movements are executed,—namely, thrusting the needle into the tissues, and drawing it out on the other side. These may well be called the first and second positions. In the first position the needle is held between the thumb and index finger and driven in by the third; in the second position the shank of the needle is seized by the wet, slippery fingers of the operator and drawn the rest of its length through. In the first position all the force required is readily obtained, and it is with this object that the needle shown was constructed, its blade being sufficiently broad to cut an opening through which the suture can be readily drawn.

Fig. 9.



Bone-forceps.

Fig. 10.

Flap-needle.

Control of Hemorrhage.—The control of hemorrhage is best accomplished by the use of the Esmarch bandage. To drain the limb of blood by elevation, as particularly advocated by Mr. Lister, employing only the circular band of Esmarch, is probably the most satisfactory way to employ it. The reactionary hemorrhage is certainly much increased by using the continuous rubber bandage, and causes increased delay in controlling general oozing, without saving for the patient much blood.

In using the circular tube or heavy flat band a word of warning will not be out of place. The nerve-lesions which from time to time have been reported as following the use of the Esmarch circular band will probably seldom occur if a simple mechanical proposition is remembered. One turn of this heavy elastic band around a limb, drawn only moderately taut, exercises a powerfully constricting force, and each succeeding turn almost doubles that of the preceding. In demonstrating this force I have not infrequently taken a number of turns with this band around a block of wood, with the result of making quite a deep furrow in it; and we all know how easy it is to cause very painful constriction of a finger by repeated turns of a small rubber band. Therefore, in applying Esmarch's constricting band, particularly to the soft, yielding tissues of children, great care must be exercised not to get too much pressure. Any one who has not experimented much in this matter will be surprised to find how little force it is necessary to exercise to arrest the pulsation in the principal artery, and with this controlled there will be very little chance of leakage through any smaller vessels.

Formation of Flaps.—With a clear idea in his mind of the shape the flap is to be and the position it is to occupy, the surgeon enters the point of the knife straight into the limb at the opposite side from which he is standing, and, with firm steady pressure, carries it in an easy curve to the other side, dividing, if possible, all the tissues down to the deep fascia. If the flap is to be an integumentary one, it is to be rapidly dissected up by light touches with the point of the knife. The flap on the other side, if also tegumentary, is to be formed in a similar manner. If it is to be made by transfixion, the knife is entered at one of the angles already made, is carried behind the bone, its point being made to emerge from the other angle, and by a sawing movement it cuts through the tissues at the back in such a manner as to form a flap of the required length.

Division of the Bone.—All of the larger bones and usually the smaller ones are divided with a saw, which has already been described. Division of a single bone is accomplished in the following manner. Having selected the point which is to be divided, the knife is carried around its entire circumference, and the bone is made bare of periosteum in what is to be the track of the saw. The heel of the saw is made to bear lightly upon the bone, and, the surgeon directing its course with the thumb of the left hand, the instrument is drawn backward in order to cut a shallow slot. With the limb held very steadily both above and below the point of incision, the saw is made to travel slowly and evenly most of its length until the cut is almost completed, when a few short movements finish the division. When the bone is sawn nearly through, care must be taken not to press its distal extremity either upward or downward, but to give it just enough support to hold the weight of the limb; as in the former instance the saw will be pinched, through closure of its slot, and in the latter the bone will snap off, either leaving an ugly splinter or taking one out of the retained extremity of bone. I incline to the belief that the bone is usually sawn through too rapidly, the surgeon, if he is at all agitated, rather hastening to get through with this step of the operation. With the view of determining how hot bones can be made with the saw, I have sawn through fresh beef-bone with great rapidity, at the same time letting my saw become jammed a little, with the result of getting a decidedly burnt odor of the cut surface; and, as charred bone is exceedingly prone to become necrotic, I am not sure but that we may find in this the cause for the frequent necrosis of a delicate shell of bone corresponding with all or a portion of the sawn surface.

Arrest of Hemorrhage.—In all amputations the principal vessels can be tied before the removal of the tourniquet or other controlling appliance. In the larger amputations the open mouth of the main artery stands out clear and plain. It should be seized with the artery-forceps, and with the finger-tip isolated from its connections, not only in order to avoid tying with it any part of its accompanying nerve, but also because the action of the ligature upon its coats will thereby be best accomplished. The catgut used should be chromicized sufficiently to last two weeks, and for a large vessel should be No. 3, for a smaller vessel No. 2, down to branches the size of a digital artery, for which No. 1 is appropriate. A double reef-knot should be made for ordinary vessels, and a treble knot for the femoral or brachial. After the tying, the surgeon seizes the free ends of gut with his left fingers, while he places his right thumb upon the knot in such a way that its nail shall act as a gauge for the assistant to place the blade of his scissors upon in cutting through the gut an eighth of an inch from the knot. The principal vein is then to be treated in a similar manner.

After removal of the tourniquet numerous small branches will make their presence apparent either by streams of blood or by points of dark clot. In the latter a little scraping should be done in order to coax them to bleed. If the patient's condition is good, it is well to delay for a while the approximation of the flaps,—that is, not to hurry with the closure of the wound,—as it is far better that reactionary hemorrhage should occur under observation than in the dressing.

General slight oozing may be arrested by the use of hot water applied with sponges at a temperature a little too high to be borne by the fingers. A much more efficient agent, however, is prepared chalk. This I have used in about a dozen and a half major operations in the past six weeks, and have been much gratified with its effect. It should be sterilized by heat and kept in a salt-pot. When the hemorrhage has been sufficiently arrested with ligatures, the chalk is freely dusted over the bleeding surface, and, after being allowed to remain two or three minutes, is completely washed off by the irrigating stream.

The effect upon muscular tissue was in the beginning a great surprise to me. It assumes a harsh, parched surface, looking and feeling as if some powerful irritant had been applied; the color changes to a dusky red, and the oozing ceases. There is no evidence, however, that any irritation has been caused, and I have failed to observe that primary union is in the least retarded by its application.

Approximation of Flaps.—In the larger flaps, it being important that no open space containing air should remain, it will often be found best to introduce two or more deep sutures half-way up to the base of the flap. These should be tied very loosely, so that they shall not interfere with the free circulation of the blood in the tissues included within them, their only object being to bring the internal surfaces of the wound into contact. Neat coaptation of the edges of the flaps is best accomplished by interrupted sutures of catgut, in a manner which will be described in treating of the several amputations. I prefer also giving the details of the dressing of each stump in its proper place, in order that the reader shall not be obliged, perhaps when hurried, to refer to these matters under another heading.

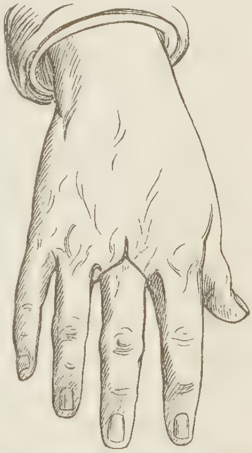
SPECIAL AMPUTATIONS.

UPPER EXTREMITY.

Fingers.—If the tip of a finger is cut off at a point not higher up than the middle of the nail, no operation need be done, provided the injury has been produced by a clean cutting instrument, as an axe or a knife. If the wound is a contused one, caused by cog-wheels or the like, it may be necessary to cut away the edges which have been destroyed. Should the lesion extend a little higher up, the distal phalanx becomes involved, and a sufficient portion of it must be removed to countersink it a trifle below the level of the surrounding tissues. At a point between the base of the nail and the distal joint, though clean wounds often cicatrize leaving a stump free from tenderness when no flaps have been made, it is generally desirable to make a sufficient attempt at flaps to effect partial approximation. So great is the vitality of the fingers, and so important is it that not a fraction of an inch should be unnecessarily sacrificed, that it is better to leave a wound not completely approximated than to remove good tissue in order to form perfect flaps. For the same reason it is always proper to amputate in the continuity of a phalanx rather than to go higher up in order to reach a joint.

Formal amputation at the joint of any digit, with the exceptions afterwards to be mentioned, is done by forming a short oval posterior flap with a long anterior. Amputations at the metacarpo-phalangeal articulations may also be practised by antero-posterior oval or by lateral flaps. At this joint of the middle finger a modified oval flap operation (Fig. 11) is often done. Entering the knife at the back of the joint, it is carried obliquely downward and forward and is made to encircle the finger and return to the starting-point by a single sweep.

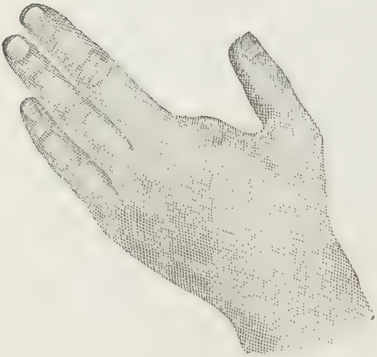
Fig. 11.



Incision for metacarpo-phalangeal amputation. (After Agnew.)

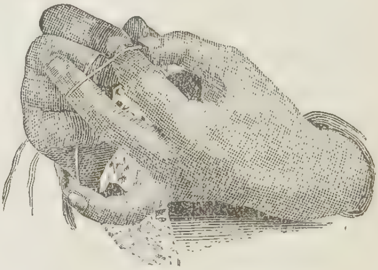
After disarticulation the head of the metacarpal bone is frequently sawn off, particularly in cases where the individual is not obliged to do manual labor. The object of removing the head of the metacarpal bone is to make the deformity less noticeable, as it allows of closer approximation of the adjoining knuckles. Among the working classes in adults I do not advise this, as the strength of the hand is thereby somewhat diminished. In children, however, it is advisable. The same is true of amputation at the metacarpo-phalangeal articulation of the index finger. Fig. 12 illustrates an amputation of the index finger in a little girl operated upon by the writer, where the head of the metacarpal bone was removed simply to improve the appearance of the hand. Fig. 13 is made from a photograph representing her crocheting, and so easy is the line from the middle finger to the thumb that it is at first sight difficult to realize that the index finger is wanting.

FIG. 12.



Result after amputation of the index finger, with removal of the head of the metacarpus.

FIG. 13.



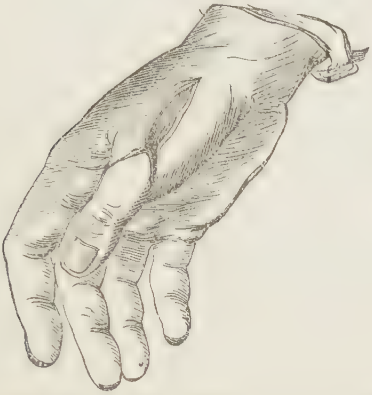
The same, doing needle-work.

In amputating fingers it will be found very convenient to arrest hemorrhage by employing a rubber band, as the circular bandage of Esmarch. One of these little bands can readily be applied doubled upon itself often enough to give the requisite constriction, and it very much facilitates the performance of the operation, by keeping the tissues dry. Particularly is this the case when an amputation is done for disease of the bone, where it is important to observe to what extent the disease has involved the latter. After the amputation has been completed the band is removed, and the two arteries which will be found on the palmar surface at the inner and outer sides are ligated.

A small drain consisting of two or three strands of catgut is placed directly across the bottom of the wound. The latter is brought together by three or four interrupted catgut sutures. A delicate strip of protective is placed over the wound, the stump is dusted with iodoform, and a dressing of corrosive sublimate is made to envelop the stump; upon this a layer of corrosive-sublimate cotton is applied, covered snugly with a double thickness of oiled silk. The hand and forearm are retained to a palmar splint which has been comfortably padded with oakum and patent lint.

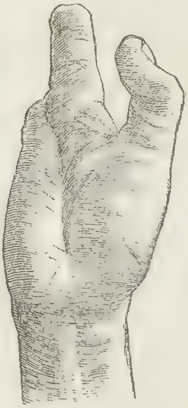
Amputation of the Carpus and the Metacarpus.—Amputation of the thumb and its metacarpal bone is performed by entering the knife at the base of this bone and carrying it straight downward on a line corresponding with the junction of dorsal and palmar skin until the metacarpophalangeal joint is reached, where the knife is made to encircle the digit obliquely and return to the straight incision (Fig. 14), as in the amputation of the middle finger just described. The bone is then dissected out, disarticulated at its carpal articulation, and approximation of the flaps is readily and perfectly accomplished, leaving behind all the muscular tissue composing the thenar eminence. With this stump a certain degree of opposition to the fingers remains.

FIG. 14.



Lines of incision in removing the thumb with its metacarpal bone. (After Agnew.)

FIG. 15.



Stump after removal of a wedge-shaped piece from the central portion of the hand. (From a cast in the writer's collection.)

Where the injury has involved some portion of the hand which precludes the performance of any formal operation, it is perfectly proper to cut away with the saw or the forceps all bone which is hopelessly damaged or which prevents approximation of the soft parts. In Fig. 15 may be seen the result of one of these irregular operations, done by the writer at the Episcopal Hospital. The boy's fingers were caught in cog-wheels, the damage extending well into the middle of the hand. The operation done here consisted in sawing out, without the least regard to joints, a wedge-shaped portion of bone, including parts of the carpus and metacarpus, the apex of the wedge being very close to the wrist-joint. The outer and inner portions of the hand were brought together, with the result of giving the boy, who worked in a mill, a strong and useful hand.

In amputations of the metacarpus along with portions of the carpus, hemorrhage may be controlled by the pressure of the fingers and thumbs of a reliable assistant upon the radial and ulnar arteries, or, if sufficient help is not at hand, by the application of a tourniquet to the brachial artery. It would be useless to attempt to describe the vessels which might need ligation after removal of portions of the hand. Both the deep and superficial palmar arches, when cut, usually require ligation at both severed extremities. To control general oozing from vessels too small to ligate, the application of prepared chalk or hot water will be found of great value.

So, too, it would be out of the question to lay down any rules for the approximation of the flaps: here, as in all irregular amputations, there is ample scope for the exercise of the surgeon's snap ingenuity in making the best use of the tissue retained, and in forming a stump which is free from tension and which will afterwards give the patient the best use of his limb. A skein of catgut, consisting of half a dozen strands, is placed in the bottom of the wound, emerging at its angles, for drainage. Approximation is effected by the introduction of interrupted sutures at intervals of about half an inch. A narrow strip of protective is placed along the line of the wound, iodoform is freely dusted upon it, and a pad consisting of about twenty-four layers of corrosive-sublimate gauze is applied, covered with a thin layer of corrosive-sublimate cotton, and closed in oiled silk. The hand and forearm are retained to a palmar splint, which has been carefully padded so that it shall give good support without undue pressure at every point of contact.

Amputation at the Wrist-Joint.—Though amputation at the wrist-joint is an operation which is seldom performed, it may become necessary, either for disease involving the carpus but not extending into the radio-ulnar articulation, or for injury. The loss of function consequent upon the changes which occur in this latter joint is not sufficient to warrant the performance of an amputation higher up. For, although pronation and supination may be to some extent interfered with, the resulting stump is likely to be more useful than if all connection between the radius and ulna is severed.

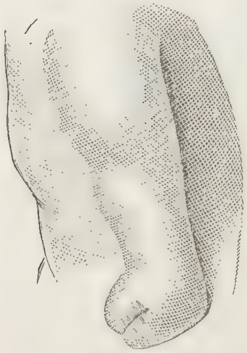
Operation.—After the application of a tourniquet to the brachial artery, a long anterior oval flap should be cut, extending half-way into the palm. This may be done by transfixion, including all the tissues down to the bone, or by carrying the incision from without inward. The horns of the incision correspond with points just below the styloid process of the radius on the outer side, and half an inch below the styloid process of the ulna on the inner side. A short posterior flap is then cut upon the dorsum, the flexor and extensor tendons are divided, and the joint is laid open with the point of the knife, entering the capsular ligament while the hand is firmly flexed by the operator. The lateral ligaments are then divided, and the operation is completed by severing any tendons which remain undivided. Before removing the tourniquet the larger vessels, including the radial, ulnar, and interosseous, should be secured. Then, removing the tourniquet, any small arteries which bleed must be carefully ligated. A drainage-skein consisting of six strands of catgut being placed in the bottom of the wound, and extending out of the external and internal angles, the flaps are approximated by interrupted catgut sutures placed at intervals of half an inch apart. A thin strip of protective is placed over the line of incision, the stump is freely dusted with iodoform, and the dressing of corrosive-sublimate gauze, consisting of about twenty-four thicknesses, is neatly folded around it. A layer of corrosive-sublimate cotton outside of this, covered with oiled silk, completes the dressing, and the forearm is placed upon a comfortably-padded straight splint.

Amputation of the Forearm.—The two common methods of performing this operation are either by antero-posterior flaps, or by the method of Teale, presently to be described. In the oval flap method two flaps, each corresponding in length with the diameter of the limb, including the whole integument, are dissected up, and the muscles are divided by a circular incision made by a single sweep of the knife. A catling is then passed between the radius and ulna at a point on a line with the circular incision, and all the interosseous tissues are divided. A three-tailed retractor is then employed to hold back the flaps, and the bones are sawn through simultaneously. The radial, ulnar, and interosseous arteries, and occasionally some small muscular branches, require the ligature.

Teale's Amputation.—This amputation is the only one which requires for its accurate performance that the lines of incision shall be mapped out upon the skin by an aniline pencil. It consists in the formation of two rectangular flaps, a shorter and a longer one. The shorter flap invariably contains the blood-vessels. The longer flap in length is one-half the circumference of the limb at the point of amputation. The shorter flap is one-third the length of the longer. These flaps are made to include all the tissues down to the bone. The catling is used to divide the interosseous tissues, a retractor is introduced as in the oval flap method, and the bones are divided at the base of the flaps. The longer flap being reflected upon itself and its terminal extremity being brought into apposition with that of the shorter flap, the cicatrix occurs at a point remote from the end of the stump, and the latter becomes smooth and symmetrical. To obtain this approximation, one angle of the long flap is stitched with an interrupted suture to the corresponding angle of the short flap. The opposing angles are treated similarly. An interrupted suture is placed in the middle, and the sides are brought together in such a way as to unite the long flap, near its base, to its reflected terminal extremity. Intermediate sutures are then introduced at intervals of about half an inch, the drainage catgut being carried through the upper angle of the wound. Narrow strips of protective are placed over the wound, the line of which is shaped like the letter H. After dusting iodoform freely over the stump, a dressing of corrosive sublimate cotton is made to envelop it, and oiled silk is carefully folded round the entire dressing. The stump is retained to a carefully-padded splint extending up to the elbow-joint.

Amputation of the Elbow-Joint.—Though the nature of the injury and the condition of the adjacent soft parts often may necessitate the performance of an irregular amputation at this articulation, the formal operation consists in the formation of a long anterior and a short posterior flap, as follows. The operator, placing his thumb and index finger over the internal and external condyles of the humerus, enters the blade of a long amputating knife just below and slightly anterior to these points. The knife is then carried downward, closely hugging the bones, a distance equal to the diameter of the forearm, when it is curved outward quite abruptly. From the angles of this incision, a cut is made straight across the back of the forearm just below the olecranon process. The transfixing incision frequently opens the capsular ligament of the elbow-joint, when the disarticulation is readily accomplished by a few light touches of the point of the knife while the forearm is kept rigidly extended. A saw is then placed in the greater sigmoid cavity of the ulna, and the bone is divided, leaving the olecranon behind. This amputation leaves a very useful stump and one to which an artificial appliance may be adapted, though not nearly so advantageously as if the smallest part of the forearm is retained. Fig. 16 shows an amputation of the forearm performed by the writer at the Episcopal Hospital, in which very small portions of the radius and ulna were retained, but the patient had complete flexion and extension of the stump, and the function of his limb was thereby very much better than it would have been had the amputation been performed at the elbow-joint. I have seen a well-digger, with this most excellent substitute for a hand, lift a heavy bucket of sand from the bottom of a well with great ease, handling the rope almost as readily as with his sound limb. I have also seen a man row a boat holding the handle of one oar in this flexure of his elbow; and to see a man holding one rein with this stump in driving is a matter of common observation.

Fig. 16.



Stump resulting from amputation just below the elbow-joint.

Amputations of the Arm.—Amputations of the arm from the elbow to the shoulder are performed by the oval flap method with circular division of the muscles, by oval flaps made by transfixion, or by the rectangular flaps of Teale as hitherto described.

Oval Flap Method with Circular Division of the Muscles.—Entering the knife at the outer aspect of the arm, an incision, which is made to include the skin and the superficial fascia, is carried down in a curvilinear direction a distance equal to two-thirds the diameter of the limb, whence it ascends the inner aspect of the arm to a position opposite to the starting-point. A similar cut is made at the back, and the anterior and posterior integumentary flaps are rapidly dissected up with light touches of the point of the knife. Held back by an assistant, these flaps are kept well out of the way, while the knife is made by a single circular sweep to divide all the muscles down to the bone. A two-tailed retractor is then placed in position, and the humerus is sawn through at a point a little higher up than the level of the circular division of the muscles. The brachial artery first requires the ligature, and the ligation of the smaller muscular branches, according to the point at which the amputation is performed, completes the operation.

Operation by Transfixion.—The knife is entered at the inner (right) or outer (left) aspect of the arm, penetrating directly to the bone; its point, on reaching the latter, is made to hug the humerus closely, the tissues being grasped meanwhile and carried forward by the left hand of the operator, and it is thrust through a point on the opposite side corresponding to that of entrance. By a sawing motion the blade is then carried downward and gradually curved towards the surface to form a flap two-thirds the diameter of the limb. A posterior flap of like form and size is made in a similar manner by re-entering the knife at the angle of the wound and carrying it behind the humerus. Before removing the tourniquet a ligature should be applied to the brachial artery. As this vessel occasionally divides high up into two trunks, it is a proper precaution to be prepared to find two arteries in the arm, and not to omit ligating one of them, on the supposition that it is a vein.

Operation of Teale.—The rules for the formation of the flaps in this operation, as just laid down for amputation of the forearm, are carried out in a similar manner on the arm. In order that the shorter flap shall contain the principal blood-vessel, it is made upon the inner side. After the ligation of all vessels which bleed, and the control of any general oozing which continues, the flaps are ready for approximation. This is accomplished, after the introduction of a skein consisting of about one dozen strands of rather heavy catgut for drainage, by inserting interrupted catgut sutures at intervals of about three-quarters of an inch. The line of the wound is then covered throughout its length with a half-inch strip of protective, iodoform is freely dusted over the stump, and corrosive-sublimate gauze consisting of about three dozen thicknesses is applied. Outside of this a generous layer of corrosive-sublimate cotton is neatly retained by a piece of oiled silk or two sheets of wax-paper, and a roller bandage completes the dressing.

Amputations at the Shoulder-Joint.—Amputation at the shoulder-joint in children, as in adults, may be practised by the methods of Larrey, Spence, Dupuytren, or Lisfranc, or, particularly when done for injury, by a modification of either of these. The method of Larrey, when practicable, is usually to be preferred.

Larrey's Operation.—Entering the point of the knife just beneath the acromion process of the scapula, an incision reaching to the bone is carried straight downward a distance corresponding to the diameter of the arm. Curving off from this point forward and backward, two other cuts are made, approaching each other on the inner side, but both falling short of the brachial artery. The head of the bone, covered by its capsular ligament, is then brought clearly into view by dissecting up these oval flaps in front and behind. Pressing the arm firmly to the side of the body, the capsular ligament is put upon the stretch, and is readily divided by the point of the knife. By forcible rotation of the arm inward the tendons of the supra-spinatus, infra-spinatus, and teres minor are put upon the stretch, and are divided. By rotation outward the tendons of the biceps and of the subscapularis are in like manner made tense, and divided, when the head of the bone slips easily out of its socket. A long knife is then placed in position, blade downward, behind the humerus, preparatory to dividing the remaining tissues. An assistant now grasps with his thumbs and fingers the uncut portion of the flap containing the blood-vessels. The knife is carried downward, closely hugging the bone, until it reaches the curved incisions which have already been made, when its course is directed in their line abruptly to the inner side, the assistant's fingers having followed it to this critical point. The limb thus severed leaves the flap containing the blood-vessels in the hand of the assistant. The brachial artery is promptly seized with the forceps and tied; the brachial veins require separate ligatures; other vessels, including the circumflex, also require ligation.

Spence's Operation.—Spence's operation differs from Larrey's mainly in that the perpendicular incision is started anterior to, instead of on a line with, the acromion process. The object of this modification is to secure a somewhat more shapely stump, and also to sever the smaller branches of the circumflex artery instead of the larger ones. After forming the anterior and posterior flaps, dissecting them up, and disarticulating the head of the bone, the operation is completed in a similar manner to that of Larrey.

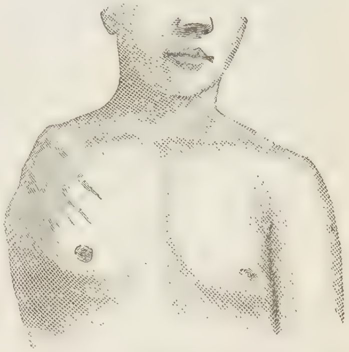
Dupuytren's Operation.—The point of the knife is introduced at the back of the shoulder behind the acromion process, and is carried straight forward through the mass of tissue overlying the head of the humerus, which has been picked up by the left hand of the operator, to a point just outside the coracoid process of the scapula. In performing this transfixion, the capsular ligament upon its outer side is apt to be opened. An oval flap is then formed of muscle and integument, which extends down as far as the insertion of the deltoid, the head of the bone is disarticulated as in the method of Larrey, and the posterior flap is quickly formed, while the vessels are controlled by an assistant. The cicatrix which results is transverse instead of vertical.

Lisfranc's Operation.—The arm being elevated, in order to relax the tissues of the shoulder, the point of a long knife is entered midway between the coracoid and acromion processes, and is carried in a direction backward and downward, so that it will emerge at the posterior fold of the axilla. A musculo-cutaneous flap is then cut corresponding in length to one-third the diameter of the arm. The head of the humerus is readily dissected out, and, being raised from the glenoid cavity, preparation is made to cut the inner flap. An assistant places both thumbs behind the bone, upon the vessels, while his fingers are used for counter-pressure in the axilla. The surgeon then re-enters his knife, and as he carries it down along the bone the assistant's thumbs closely follow its track while a short internal flap is formed.

Amputation of the Entire Upper Extremity.—This operation, which includes the removal of the scapula and clavicle, has seldom been performed. When the injury or disease will permit, the operation consists in dissecting out the scapula and clavicle after amputating at the shoulder-joint. The scapula is removed through an incision carried along the length of its spine, the supra- and infra-spinous mass of muscles being dissected up, and a few bold sweeps of the knife readily separate the bone from its loosely-adherent attachments beneath. The clavicle is removed through an incision which reaches from its sternal articulation outward. After dividing the ligaments at this joint, it is in like manner dissected away from the tissues surrounding it.

Portions of this operation are not infrequently required after injury, in order to secure proper approximation of the flaps when the lesion has extended too far to render a shoulder-joint amputation possible. Fig. 17 represents the result of one of these partial upper-extremity amputations. Although the subject was an adult, not a minor, it serves equally well for the purposes of demonstration. The patient was operated upon by the writer at the Episcopal Hospital. His shoulder had been caught in cog-wheels, and the destruction of the integument had extended so far inward that, in order to make flaps which would sufficiently cover the gap, it was found necessary to remove the acromion process along with part of the spine of the scapula and the outer half of the clavicle. The patient made a good recovery, with a comfortable stump, the peculiar form of which is well shown in the drawing.

Fig. 17.

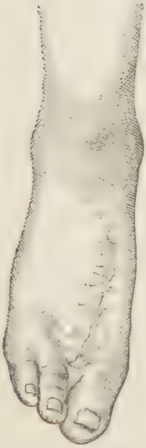


Stump following amputation of the arm along with parts of the scapula and clavicle.

AMPUTATIONS OF THE LOWER EXTREMITY.

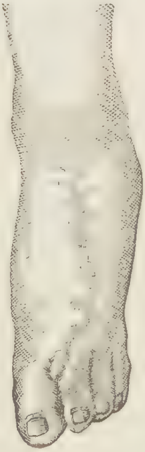
Amputations of the Toes.—What has been said of amputations of the fingers is generally applicable to amputations of the toes. In amputations of the latter, as in amputations of the foot, it is very desirable to avoid, when possible, the placing of a cicatrix anywhere upon the plantar surface. Long anterior flaps, therefore, are to be made whenever practicable. As in the hand, irregular operations, including removal of the destroyed tissues, independently of articulations, are proper. Fig. 18 represents the result following the removal by the writer of the second and third toes, along with their metatarsal bones. Fig. 19 represents a foot after the removal of the second toe and its metatarsal bone.

Fig. 18.



Foot after removal of the second and third metarsal bones and their toes.

Fig. 19.

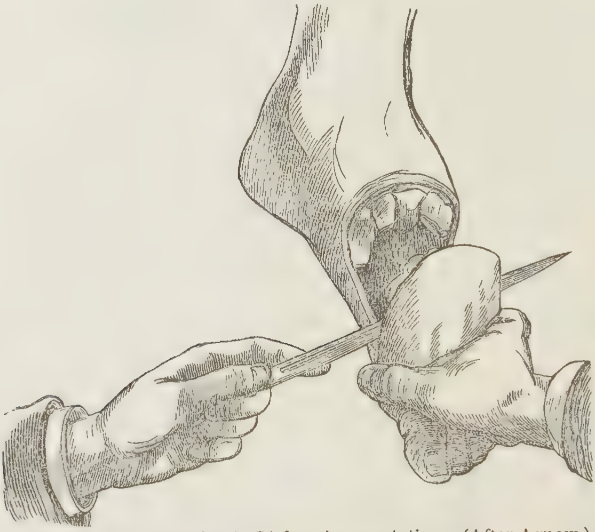


Foot after removal of the second metatarsal bone and its toe.

Two important facts must be borne in mind in determining the propriety and character of these irregular operations about the foot. One is the important part which the inner side of the foot plays in locomotion. A patient in whom the ball of the foot and the great toe have been preserved will often walk with almost no limp, and with a gait which is very much in contrast with that of an individual who, having had all his other toes preserved, has lost the great toe. This fact justifies the surgeon in taking great risks of sloughing, and even of a second operation, in his attempts at preserving this portion of the foot. The other important thing to be remembered is that the foot, unlike the hand, will not usually be given the kind of subsequent care by the patient which will permit a tender or tense cicatrix to become strong and to stand pressure.

Tarso-Metatarsal Amputations.—*Lisfranc's Amputation.*—With the index finger and thumb, two points are sought on the inner and outer aspects of the foot, which serve as a guide for the inner and outer angles of the anterior flap. These are the apex of the internal cuneiform bone and the tuberosity of the metatarsal bone. Between these a short flap with its convexity downward is made, the integument is dissected back, and, with strong pressure made upon the foot, the tarso-metatarsal joints are opened. The articulation of the second metatarsal bone, being higher up and out of line with the others, requires a little careful touching with the point of the knife, in order to free it. The joint being thus opened, disarticulation is completed by a few light touches of the knife. The plantar flap is then formed by carrying the knife close to the bone downward to a point on the inner side which includes the tissues forming the ball of the foot, and on the outer side to a point a little short of this. The object of this obliquity in the plantar flap is to cover properly the end of the stump, which is thicker on its inner than on its outer side. A modification of this operation, called, after its designer, Hey's, leaves the base of the second meta-

FIG. 20.



Formation of plantar flap in Lisfranc's amputation. (After Agnew.)

tarsal bone behind, by cutting through the shaft of the bone with a saw, instead of disarticulating it.

Chopart's Amputation.—In this the astragalus and calcaneum are the only bones of the tarsus preserved. The anterior flap is formed by entering the knife over the tuberosity of the scaphoid bone on the inner side, carrying it downward across the foot, and in an easy curve backward to the tuberosity of the fifth metatarsal bone. After dissecting up this flap, including in it skin and superficial fascia, a few light touches with the point of the knife, while the foot is pressed forcibly downward with the left hand of the operator, will readily open the joints between the head of the astragalus and the scaphoid and between the calcaneum and the cuboid bone. Placing the blade of the knife between the freshly-disarticulated bones of the tarsus and the plantar tissues, a posterior flap is cut by a gentle sawing movement of the knife. This flap should be longer on the inside than on the outside, and should extend down almost as far as that for Lisfranc's amputation,—viz., to the tissues forming the ball of the foot. Before removing the tourniquet, the dorsalis pedis and several plantar branches, varying somewhat according to the exact points of incision, of the posterior tibial artery should be ligated. A drainage catgut skein should be placed in the bottom of the wound, emerging from the inner and outer angles, and, if suppuration is expected, a portion of it may well be carried out through a central button-hole pierced in the plantar flap. Neat approximation is effected by points of catgut suture placed at intervals of about half an inch. A narrow strip of protective is made to cover the length of the wound, which is afterwards dressed in the usual way, with a free sprinkling of iodoform, about two dozen thicknesses of corrosive-sublimate gauze, a gauze bandage, a layer of antiseptic cotton, and wax-paper. The retaining bandage should be carried up as far as the knee, in order to control and give support to the muscles of the calf.

Amputations of the Ankle-Joint.—*Syme's Amputation.*—In this operation the entire foot, along with the external and internal malleoli, is removed. An excellent stump and one which stands pressure admirably well results, as the strong dense tissues of the heel are utilized in making a long posterior flap. Entering the point of the knife over the external malleolus, a curved incision is carried across the top of the foot to a corresponding point on the opposite side,—namely, not to the tip of the internal malleolus, but to a point one-third nearer the heel. The angles of this cut are connected by an incision carried straight across the sole of the foot, when the os calcis is carefully dissected out from the tissues of the heel, to which it will be found very firmly attached. The ankle-joint is then opened from before backward, and, after disarticulation, the lower extremities of the tibia and fibula are sawn off at a point which will include a thin slice of the articular surface of the former. In doing this, care must be taken not to wound the posterior tibial artery. The posterior flap should be carefully applied to the bones of the leg during the approximation, in order to avoid leaving a pocket in the stump. Approximation is effected by the introduction of points of catgut suture at intervals of half an inch. The wound is dressed as in Chopart's operation.

Pirogoff's Amputation.—In this the posterior half of the calcaneum is retained in the heel-flap, and is turned up and applied to the bones of the leg. While not so applicable to cases of disease of the bone as Syme's operation, because there is always the risk of the caries attacking the retained portion of the heel-bone, it certainly possesses the advantage over the latter of giving a decidedly longer stump. This, though a matter of no consequence to the artificial-limb manufacturer, as the length of the Syme's stump gives him sufficient length for the application of an artificial foot, is well worth considering in the interest of a poor patient. With a Pirogoff stump a man can get on, as a rule, perfectly well without an artificial foot; indeed, I recall one who, with an ordinary shoe and a little oakum stuffed in the heel, walked with a limp so slight that the true nature of his deficiency would hardly suggest itself. But this amputation, to give its best result, must be carefully and dexterously performed.

The anterior flap is formed by a slightly convex incision extending from the lower point of the internal to the tip of the external malleolus. The angles of this cut are connected by an incision carried straight across the sole of the foot. The ankle-joint is opened and the astragalus disarticulated. Next comes the division with the saw of the calcaneum and of the articular extremities of the tibia and fibula, upon the accuracy of which the usefulness of the stump will largely depend. Applying a butcher's saw just behind the articulation of the astragalus with the os calcis, the latter is sawn through in a direction downward and slightly forward; the saw is then applied to the anterior aspect of the tibia, and is carried through a point just high enough to include all of the articular cartilage along with both malleoli in a direction backward and slightly upward. This oblique section of the os calcis and of the bones of the leg causes the turn the former makes in being applied to the latter to be slightly less than a quarter of a circle. In this way the dense tissues of the heel will be to a great extent retained, to receive their accustomed pressure, instead of the much less able structures upon its posterior aspect. Some surgeons prefer mortising the fragment of bone between the malleoli, and so much does the size of the os calcis vary in relation to the width of the socket at the ankle that occasionally it will be found to fit very nicely. When it is intended to do this, more of the os calcis must be sawn off, in order to avoid bony tension after approximation. Approximation is accomplished by the introduction of interrupted catgut sutures at intervals of half an inch, after placing a catgut drain in the bottom of the wound. The wound is dressed as after Syme's amputation, except that a card-board splint is nicely adapted to the posterior aspect of the limb.

Amputation of the Leg.—In cases where the involvement of the tissue from disease or injury extends too high for the performance of Syme's amputation, the point of election is now usually admitted to be not higher than the junction of the middle with the lower third; for, although at this point not so much tissue exists for the formation of an ample cushion to cover the bone, with properly-formed flaps the resulting stump readily stands the retraction caused by the socket of the artificial limb, and the increased leverage gained is of manifest utility in locomotion. The operation which at this point gives the best results consists of the long anterior oval flap of integument, reflected backward upon a short musculo-cutaneous flap; the latter can well be made by transfixion. Where the damage to the integument precludes the formation of a long anterior flap, antero-posterior oval flaps of equal length composed of integument, with a circular division of the muscles, is an operation which has been regarded favorably in this country, albeit the cicatrix occurs over the ends of the bones. It must be admitted that Teale's amputation, as applied to the leg, is rather prodigal of tissue, and particularly so to the leg of a muscular subject.

By the long oval anterior flap method the knife is entered a short distance to the outer side of the spine of the tibia, and carried in a direction downward a distance corresponding to the diameter of the limb at the starting-point, when it sweeps in an easy curve across the front of the leg, and upward an equal distance on the inner side. The plane of this anterior flap should be slightly inverted,—*i.e.*, the external angle of the wound should be on a plane anterior to that of the internal angle,—in order that the spine of the tibia shall occupy a position in the middle of the flap. The detachment of this flap from the deep fascia is very readily accomplished by a few light touches of the knife. Entering the latter at either angle which is more convenient, its blade is passed behind the fibula, brought out on the other side, and curved rather abruptly backward, in order to make the short posterior flap. A catling is then employed to divide the interosseous tissues, and, everything being held well out of the way by means of a three-tailed retractor, the bones are sawn through. The saw should first be made to engage itself in the tibia, when its line of motion is altered so that it will cut through the fibula, after which the section of the tibia is to be completed. Before removing the tourniquet, ligatures should be applied to the anterior tibial, interosseous, and posterior tibial arteries.

At this point I cannot but recommend a procedure the advantage of which has been criticised. It is the sawing off of the prominent right angle of the spine of the tibia. It has been urged that by so doing two angles of bone, instead of one, are made to press upon the anterior flap. True, but very obtuse angles they are, and in old subjects particularly, where every care has been taken to give the stump proper support, I have occasionally been much annoyed to see this angle of bone finding its way through the skin. After approximation by interrupted catgut sutures at intervals of three-quarters of an inch apart, the line of the wound will be found to be well back of the end of the stump.

Where the injury or disease has involved the limb so high up that there is not sufficient sound integument to form oval flaps, a modification of the old circular amputation will be found very economical. Entering the knife at the inner or outer aspect of the leg at a point corresponding to one-half its diameter, a very slightly curved incision is carried across the front to the opposite side; and a similar cut is made at the back, thus forming two very flat-ended flaps. These are dissected up a considerable distance above the position of their angles, when a circular division of the muscles is made by one sweep of the knife. A catling is then thrust between the bones and a three-tailed retractor is introduced. The division of the bones with the saw should be made from one-half to one inch higher up than the plane at which the muscles were divided. This operation is particularly applicable just below the knee, when there is no room to perform an amputation by any other method without losing the knee-joint.

Amputation at the Knee-Joint.—In the operation which I prefer a long anterior flap is made and the patella is retained. This method is, of course, much more frequently applicable after injury than for disease. Properly performed, the anterior flap falls as a hood over the condyles of the femur, bringing the line of cicatrix well back of the point of pressure, the patella usually becomes ankylosed to the femur, and a strong, tough, somewhat knob-shaped stump results, admirably adapted for the socket of an artificial limb.

The knife being entered just below and a little behind the external condyle of the femur, it is carried straight downward to a distance below the tuberosity of the tibia corresponding to the diameter of the limb at this position, when an anterior oval flap is formed by carrying it across the limb and back to a point on the opposite side corresponding to the starting-point. This flap, including the skin and superficial fascia, is dissected up as far as the patellar tendon, which, while the leg is forcibly flexed upon the thigh, is divided close to its sesamoid bone, when the condyles of the femur will be exposed to view. After completing the division of the anterior portion of the capsular ligament of the knee-joint, the lateral ligaments are severed. In effecting this disarticulation care must be taken not to divide the ligamentum mucosum, as this membrane assists very materially in retaining the thigh-tissues to the knee, for even in the cadaver, where the precaution has been taken of making the base of the anterior flap extend over two-thirds of the circumference of the knee, when this membrane is cut the thigh-tissues retract so much that the entire end of the femur is denuded and thrust out. In cutting the posterior portion of the capsular ligament it should be borne in mind that the popliteal artery is in close proximity. Whilst the leg is completely flexed upon the thigh, the blade is snugly insinuated behind the tibia, and is made to form a musculo-cutaneous posterior oval flap one-third the length of the anterior. Lateral oval flaps and triple flaps—*i.e.*, one anterior, two posterior—are occasionally used, but they would not seem to possess ordinarily any advantages over the operation above described.

Amputation of the Thigh.—The operation of Mr. Carden,[1] through the condyles, gives the longest thigh-stump of any amputation. It is described by him as follows: "The operator, standing on the right side of the limb, seizes it between his left forefinger and thumb at the spots selected for the base of the flap, and enters the point of the knife close to his finger, bringing it round through skin and fat below the patella to the spot pressed by his thumb; then, turning the edge downward at a right angle with the line of the limb, he passes it through to the spot where it first entered, cutting outward through everything behind the bone. The flap is then reflected, and the remainder of the soft parts divided straight down to the bone; the muscles are then slightly cleared upward, and the saw is applied." The condyles are then cut through at a right angle with the line of the limb. In this operation it is possible to make an exploration of the knee-joint after the formation of the upper flap. In cases of disease of the latter, before determining whether to do a resection or an amputation, Carden advises always removing the patella.

Mr. Lister prefers a modification of this method, as follows:[2] "The surgeon first cuts transversely across the front of the limb from side to side, at the level of the anterior tuberosity of the tibia, and joins the horns of this incision posteriorly by carrying the knife at an angle of forty-five degrees to the axis of the leg through the skin and fat. The limb being elevated, he dissects up the posterior skin-flap, and then proceeds to raise the ring of integument as in a secular operation, taking due care to avoid scoring the hamstrings as soon as they are exposed, and bending the knee he finds no difficulty in exposing the upper border of the patella. He then sinks his knife through the insertion of the quadriceps extensor, and, having cleaned the bone immediately above the articular cartilage, and holding the limb horizontal, he applies the saw vertically and at the same time transversely to the axis of the limb (not of the bone), so as to insure a horizontal surface for the patient to rest on. The popliteal artery and vein are then secured, and any articular or other small branches that may require it."

At any point in the thigh above the condyles, antero-posterior flaps, consisting either of integument or of integument and muscle, should be modified to suit the character of the case. Such modifications frequently become necessary after injury. Thus, the wheel of a car passing obliquely over the limb will frequently tear away a great extent of tissue on one side, while the tissues on the opposite side remain undamaged. A long lateral flap in such cases will enable the surgeon to preserve the greatest amount of tissue. When the formal operation is practised, an oval flap made by transfixion, in length two-thirds the diameter of the limb where the bone is to be cut, and a posterior flap of similar length, consisting of integument alone, or of integument and a small amount of muscular tissue, will give the best result.

---

[1] Henry D. Carden, Esq., British Medical Journal, 1864, vol. i.

[2] Holmes's Surgery, vol. iii. p. 718.

Entering a long amputating knife directly over the linea aspera, its point is carried directly to the bone, while the left hand of the operator grasps the tissues of the thigh in front, so that they will bulge forward. On reaching the bone, the point of the blade is made to ride over the femur and emerge at a point on the opposite side, to form the base of a flap which shall include the semi-circumference of the limb. The knife is then made to describe an easy curve to the front of the thigh, where it emerges at a distance from the point of entrance equal to two-thirds the diameter of the limb. Elevating the limb, the knife is placed upon the posterior aspect of the thigh at a point which will reach the extremities of the anterior cut, when it cuts at an angle of forty-five degrees to the axis of the limb. The muscles attached to the bone are rapidly dissected free, and after the application of a two-tailed retractor the saw is applied a little higher up than the angles of the wound.

After placing a thick skein of catgut drain in the latter, the flaps are coaptated by two or three interrupted sutures, placed so deeply that they shall include at least one-half the length of the flaps. In order that these deep sutures shall not interfere with the circulation in the stump, they should be tied with very little tension. The skin-edges are neatly approximated by interrupted catgut sutures placed at intervals of three-quarters of an inch. The line of the wound is then covered with a narrow strip of protective and freely dusted with iodoform; a thick layer of corrosive-sublimate gauze is retained with a gauze bandage; after which a generous layer of corrosive-sublimate cotton covered with wax-paper and retained by a roller bandage completes the dressing. If the amputation has been performed above the middle of the thigh, the retaining bandage should terminate in a spica of the groin. A nicely-fitting card-board splint occupying the posterior aspect of the thigh and terminating in a cup-shaped form, which will adapt it to the end of the stump, will add materially to the comfort of the patient in this as in other amputations of the lower extremity. The amputation performed in the manner last described makes a most admirable stump.

Amputation at the Hip-Joint.—In amputating at this articulation the two great causes of the fatality of the operation have to be combated,—hemorrhage and shock. Without enumerating the various methods which have been proposed and practised to control the former, I shall simply describe that by the elastic band, as at once the most efficient and powerful without being harmful. It should be applied in the form of a spica of the groin, in such a way that it will not slip off the flaps after the head of the femur is disarticulated. As the rules laid down by Mr. Lister for the application of Esmarch's bandage could not be improved upon, I shall quote them as he writes:[1]

---

[1] Holmes's Surgery, vol. iii. p. 722.

"An elastic band having been provided, sufficiently strong to require the full force of the surgeon to stretch it to twice its length, and long enough to encircle the upper part of the limb when in the relaxed condition, and with tapes securely connected with its ends, is placed with one end of the elastic part under the sacrum, while the tape of that end is brought round the pelvis between the crest of the ilium and the great trochanter of the side opposite to that to be operated on, and held perfectly firmly in the vertical position by an assistant. The surgeon then, standing on the side for operation, puts the band fully on the stretch in a direction transverse to the body, and brings it up into the vertical position immediately below the iliac crest. Holding it in his left hand (if the right limb is concerned), he next passes his right hand round behind the limb, which has been previously placed in the vertical position to expel its blood, and, changing hands, encircles the thigh as near to the perineum as possible, the scrotum being held well to the other side by an assistant. The surgeon's end of the elastic band being now over the groin, he takes the other tape from his assistant and ties the two tapes together in a reef-bow over the sound side.

"Another point requires attention. Two pieces of bandage, each about two feet in length, are placed longitudinally upon the skin before the elastic band is applied, one of them over the groin, the other well behind the great trochanter, the middle of each piece of bandage being in the situation where the elastic band is to go. And when the elastic band has been applied, the lower end of each of these pieces of bandage is drawn up, so as to convert them into two loops, by means of which, in the hands of a steady assistant, the elastic tourniquet is kept drawn well up both at Poupart's ligament and behind the trochanter. If this arrangement is well carried out, the whole operation, including disarticulation, may be done uninterruptedly."

Shock in this way having been prevented in so far as it depends upon the loss of blood, its remaining element, which is the division of such an extensive mass of tissue so near the trunk, can be further diminished by severing the tissues at a point more remote from the hip. Mr. Farneaux Jordan, of Birmingham, emphasizes the importance of this thus: "First enucleate the bone, then cut through the limb at any desired spot,—the middle of the thigh or below, or even below the knee." This rule, of course, relates mostly to amputations done for disease of the femur, and would seldom be applicable to an operation required by injury; but the importance of the principle should never be lost sight of.

If the flaps are so formed that the inner side of the wound, that nearer the anus, can be closely sealed to keep it aseptic, the outer side may be used for drainage to great advantage. Mr. Lister carries an incision from the back part of the great trochanter straight down the thigh a distance corresponding to the greatest diameter of the latter. He then curves it first in front, then behind through the skin and the superficial fascia, with a slight slant to the inner side. Dissecting this flap up, as in a modified circular operation, the muscles are divided where they are exposed, and the head of the bone is dissected out.

The other methods which have been adopted I shall but briefly describe. They are by oval integumentary flaps, cut from without inward, and musculo-cutaneous flaps, made by transfixion. In the former method, an anterior flap, consisting of the skin and superficial fascia, and corresponding in length to the diameter of the thigh, should be cut from a point midway between the trochanter major and the anterior superior spinous process of the ilium to a point a finger's breadth below the ramus of the pubis. At the base of this flap, after it is dissected up, the femoral artery is ligated, and also the femoral vein. With the limb elevated, a posterior integumentary flap is formed, which is made one-quarter shorter than the anterior. With a long knife a circular division of the muscles is made in front of the joint. The capsular ligament is divided anteriorly, being put upon the stretch by forced extension of the thigh, when the ligamentum teres becomes exposed to view and is readily severed by the point of the knife.

By transfixion amputation at the hip-joint can be done with great rapidity. The point of a long amputating knife is entered midway between the anterior superior spinous process of the ilium and the great trochanter of the femur, and is carried in front of the joint in such a direction that it shall emerge upon the inner aspect of the thigh a short distance below the perineum. An anterior flap equal in length to the diameter of the thigh is then formed, and the head of the femur is disarticulated. This is usually quickly accomplished, as the first entrance of the knife is apt to shave through the anterior portion of the capsular ligament. After the head of the bone is freed from its attachments, the knife is placed behind it and made to form a posterior flap about one-half the length of the anterior.

INDEX TO VOLUME III.

A.

- Abdomen, distended, in tabes mesenterica, 210.
  - in acute entero-colitis, 138.
  - in peritonitis, 270.
  - normal features of, 213.
- Abdominal affections causing enlargement of liver, 428.
  - constrictions, obstructive, 267.
  - distention from constipation, 196, 201.
    - in hernia, 240.
  - dropsy, 511.
  - enlargement, causes of, 213.
    - from tubercular peritonitis, 214.
  - glands in constipation, 215.
  - swelling in tabes mesenterica, 212.
  - tumors, 213, 732.
    - exploratory incision, 734.
  - wall, hiatus of, 658.
    - nipples on, 752.
- Abduction in hip-joint disease, 1166.
- Abnormal mobility of the knee, 1124.
- Abnormalities of the extremities, 929.
    - club-hand, 937.
    - congenital, 929.
    - contraction of digits in, 943.
    - deficiency, 933.
    - digital, 938, 941, 943.
    - hypertrophy, 930.
    - supernumerary digits, 938.
      - limbs, 938.
    - union of digits in, 938.
  - of female genitals, 741.
  - of mammary glands, 750.
  - of small intestine, 315.
- Abscess, anal, 346.
    - marginal, 346.
  - articular, 1152.
  - ascaris lumbricoides in, 226.
  - caseous deposits in, 1154.
  - evacuation of, 1155.
  - in bone, 993, 1145.
    - causation of, 994.
    - symptoms of, 994.
    - subacute, 996.
  - in hip-joint disease, 1166.
  - of hip, 1187.
  - of joints, 1153, 1155.
    - classification of, 1153.
- Abscess in bone, drainage of, 1155.
    - evacuation of, 1155.
  - of liver, 466.
  - of pancreas, age of patients, 380, 384.
    - antiseptic treatment of, 386.
    - cases of, 381, 382.
    - causes of, 382, 383.
    - description of, 381, 382.
    - diagnosis of, 381, 383.
    - drainage of, 385.
    - evacuation of, 381.
    - external fistula for, 385.
    - incision of, 385.
    - pathology of, 381.
    - prognosis of, 384.
    - rarity of, 380.
    - suturing of incision in, 385.
    - symptoms of, 383.
    - treatment of, 384, 400.
    - tuberculous, 400.
  - opening of, 1155.
  - palmar and plantar, 845.
  - para-pancreatic, 382.
